

METHODS AND DEVICE TO BALANCE RADIATION TRANSFERENCE

Cross-reference to related application

[001]. This application claims benefit of, and priority from, Singapore patent application No. 201109702-9, filed on 28 December 2011, the contents of which are hereby incorporated herein by reference.

Field

[002]. The invention relates to methods and device for heating and cooling biological material for analysis.

Background

[003]. Multiplex polymerase chain reaction (Multiplex PCR) is a modification of PCR in order to rapidly detect deletions or duplications in a large gene. In this process, genomic nucleic acid samples are amplified using multiple primers and a temperature-mediated polymerase in a thermal cycler.

[004]. Multiplex-PCR consists of multiple primer sets within a single PCR mixture to produce amplicons of varying sizes that are specific to different DNA sequences. By targeting multiple genes at once, additional information may be gained from a single test run that otherwise would require several times the reagents and more time to perform. Annealing temperatures for each of the primer sets must be optimized to work correctly within a single reaction, and amplicon size, that is, their base pair length, should be different enough to form distinct bands when visualized by gel electrophoresis.

[005]. Commercial multiplexing kits for PCR are available and used by many forensic laboratories to amplify degraded DNA samples. Commercial kits have a number of advantages over in-house multiplexing methods. Quality control measures are undertaken by the manufacturer of the kit and ensure that reactions are uniform across all kits. This avoids the preparation of PCR master mixes which require pipetting and use of multiple assay tubes, increasing the risk of operator error and contamination. This increased reliability allows profiles obtained from commercial kits to be admitted into court which is pivotal in large criminal trials. The use of specific kits over a number of laboratories also allows for profile results to be compared as long as the same STR markers have been used in each kit.

[006]. Some of the applications of multiplex PCR include: Pathogen Identification; High Throughput SNP Genotyping; Mutation Analysis; Gene Deletion Analysis; Template Quantification; Linkage Analysis; RNA Detection; Forensic Studies. The current systems available are very big and heavy machines. The machines are not able to do both real time PCR and multiplexing. The size and fragility of current systems means they are lab based and not able to be used in field conditions.

[007]. Current devices for multiplexing require several hundreds of watts to operate and around 75% of this energy goes into the heating and cooling of samples. Such high energy requirements limit the current machines to laboratory based settings where access to a continuous energy supply is available.

[008]. Real-time polymerase chain reaction, also called *quantitative real time polymerase chain reaction* (Q-PCR/qPCR/qrt-PCR) or *kinetic polymerase chain reaction* (KPCR), is a technique based on PCR, which is used to amplify and simultaneously quantify a targeted nucleic acid molecule. Real Time-PCR enables both detection and quantification. The quantity can be either an absolute number of copies or a relative amount when normalized to DNA input or additional normalizing genes.

[009]. The procedure follows the general principle of polymerase chain reaction; its key feature is that the amplified DNA is detected as the reaction progresses in real time. For standard PCR the product of the reaction is detected at its end. Two common methods for detection of products in real-time PCR are: (1) non-specific fluorescent intercalating dyes that disrupt any double-stranded DNA, and (2) sequence-specific nucleic acid probes consisting of oligonucleotides that are labeled with a fluorescent reporter which permits detection only after hybridization of the probe with its complementary nucleic acid target.

[0010]. The object of the invention is to alleviate some of the problems of the current devices and methods.

Summary

[0011]. Accordingly, a first aspect of the invention provides a method for adjusting the temperature of a sample comprising the step of heating a substrate with a laser diode light;

said light projected on to the substrate to absorb the light and convert the light energy to a heat energy thereby raising the temperature of the substrate corresponding to the intensity of the light energy, the substrate configured to transfer the thermal energy substantially homogenously to the sample.

[0012]. Another aspect of the invention provides a device for adjusting the temperature of a sample comprising: a laser diode for projecting a light to a substrate; said light adapted to be projected substantially homogeneously on to the substrate to absorb and convert the light energy to heat energy thereby raising the temperature of the substrate corresponding to the intensity of the light energy, the substrate configured to transfer the thermal energy substantially homogenously to the sample.

[0013]. Another aspect of the invention provides a method for amplifying and/or analyzing a nucleic acid sample comprising the steps of:

- a. placing the nucleic acid sample in contact with a substrate;
- b. heating the substrate to a first temperature and maintaining the first temperature with a laser diode light source; said light projected on the substrate to absorb the light and convert the light energy to heat energy thereby raising the temperature of the substrate corresponding to the intensity of light energy, the substrate configured to transfer the thermal energy substantially homogenously to the nucleic acid sample;
- c. lowering the temperature of the substrate to a second temperature and maintaining the substrate at the second temperature; and
- d. detecting a fluorescence signal of the nucleic acid sample.

[0014]. Other aspects and advantages of the invention will become apparent to those skilled in the art from a review of the ensuing description, which proceeds with reference to the following illustrative drawings of preferred embodiments.

Brief description of the drawings

Detailed Description

[0015]. A method for adjusting the temperature of a sample is described comprising the step of heating a substrate with a laser diode light; said light projected on to the substrate to absorb the light and convert the light energy to a heat energy thereby raising the temperature of the substrate corresponding to the intensity of the light energy, the substrate configured to transfer the thermal energy substantially homogenously to the sample.

[0016]. Heating the substrate substantially homogenously will ensure that the substrate is heated up quickly using a minimum amount of energy. As the method is designed to be carried out in field conditions where it is difficult to access a large power supply it is necessary to efficiently heat the substrate and thereafter transfer the heat to the sample. Generally the light should be absorbed on the substrate at least at two locations almost simultaneously to allow efficient heating.

[0017]. There are several embodiments that allow the light to be projected on the substrate. In one category of embodiments, either the substrate or the laser diode are rotated in which case the one source of light is absorbed resulting in a uniform distribution of thermal

energy on the substrate whereby the faster the spinning, the more homogenously the thermal energy distribution is over the substrate surface.

[0018]. In another category of embodiments two or more laser diode light sources are used to heat the substrate.

[0019]. In another category of embodiments the method may further comprising the step of optical manipulation of the light by focusing, collimating, splitting, diffracting, switching or reflecting to generate multiple beamlets spatially distributed and directed on to the substrate .

[0020]. One example of optical manipulation is where the light beam from the laser diode is split, diffracted and/or reflected into at least two beamlet paths allowing the light radiation to project on the substrate at two locations so that the radiated energy is absorbed and converted to heat energy thereby raising the temperature of the substrate corresponding to the radiated light intensity and transfer the thermal energy to the sample.

[0021]. In another example of optical manipulation light beam from the laser diode light source is optically manipulated to generate plurality of beamlets by splitting, diffracting and reflecting the light beam. These beamlets are spatially directed to a stationary substrate at several locations thereby resulting in a uniform generation of thermal energy on the substrate

[0022]. In another category of embodiments more than one laser diode light sources can be used and optically manipulated to generate plurality of beamlets by splitting, diffracting and reflecting the light beams.

[0023]. Preferably the method may further comprises the step of removing the light energy from the substrate to lower its temperature and maintain the substrate to a new temperature. This allows the substrate to cool via the ambient air temperature. In one embodiment the cooling of the substrate can be further assisted by actively cooling the substrate with a sprayed mist or a fan or by other methods known in the art.

[0024]. Preferably the method may further comprise the step of detecting the temperature of the substrate via a sensor not in contact with the substrate. Such a sensor may include a thermopile.

[0025]. Preferably the method may further comprise the step of detecting a signal from the sample via a sensor. Such a sensor may include a fluorescence detector or a sensor that detects a change in magnetic resonance or any sensor capable of detecting changes in a biological sample.

[0026]. Preferably the sample is nucleic acid samples. The method and device described can be used for amplification of nucleic acid samples. This has the advantage that it conforms to the traditional workflow. To conform to the traditional workflow in some embodiments the method may further comprise the steps of; cooling the substrate to in turn cool the sample; and detecting the fluorescence of the sample as known in the art.

[0027]. A device for adjusting the temperature of a sample is described herein comprising: a laser diode for projecting a light to a substrate; said light adapted to be projected substantially homogeneously on to the substrate to absorb and convert the light energy to heat energy thereby raising the temperature of the substrate corresponding to the intensity of the light energy, the substrate configured to transfer the thermal energy substantially homogeneously to the sample.

[0028]. Preferably the device is compact and light weight to allow it to be easily portable and field deployable. The device is designed to use a minimum amount of energy by efficiently heating the substrate. This is achieved by the excitation light being absorbed substantially homogeneously effectively avoiding thermal gradients to conduct a temperature corresponding to the excitation light to the substrate and transferred as heat to the sample. This ensures that the sample is heated up quickly, substantially homogeneously and using a minimum amount of energy. As the device is designed to be used in field conditions where it is difficult to access a large power supply it is necessary to efficiently heat the substrate and thereby transfer the heat to the sample.

[0029]. In one embodiment the substrate that generates thermal energy is external to the sample holder and transfers the thermal energy to the sample by radiation, conduction and convection. In another embodiment the substrate that generates thermal energy holds the sample. In another category of embodiment the substrate that generates thermal energy is suspended within the sample.

[0030]. In one embodiment a portion of the substrate that comes into contact with the light has high emissivity. In this embodiment preferably the portion of the substrate that comes into contact with the light is black. Surface properties of an opaque substrate are important. Surfaces incident to the laserdiode light should be matte-black for maximum absorption (the emissivity of a black body is 1). However, surfaces not incident to the laser diode light should not be black in order to reduce radiation losses during the heating processes (especially, heating to 95°C and maintaining 95° during the polymerase hot-start activation and the denaturation step, respectively). Reducing radiation losses at temperatures above ambient temperatures markedly reduces the overall power consumption, as less electrical/optical input power is needed to reach and/or maintain activation, denaturation, and annealing/extension temperatures. Selective (e.g. by masking) black anodization of metals (e.g. aluminum) would be one possible way to generate a matte-black finish. Alternatively, such surfaces might be generated by plating techniques (e.g. 'black gold'). One example to selectively generate a non-black surface would be by physical and/or chemical polishing.

[0031]. In one embodiment a portion of the substrate that does not come into contact with the light is non-black. Surface properties of the substrate may be important. Matte-black surfaces will radiate much more efficiently than shiny bare metal in the visible spectrum. A shiny metal surface has low effective emissivity due to its low surface area. The emissivity in the visible spectrum is closely related to color. For most materials, the emissivity in the visible spectrum is similar to the emissivity in the infrared spectrum. Preferably, the surface of the substrate that comes into contact with the excitation light is black to maximize thermal transfer from the substrate to the sample, however, the portions of the substrate that do not come into contact with the excitation light are preferably white or shiny bare metal to avoid unnecessary heat loss from the device.

[0032]. Preferably the substrate is made of a material with low density, low specific heat capacity, high thermal conductivity or high absorption coefficient. A low (thermal) mass enables fast temperature transition rates/changes. Furthermore, a low thermal mass correlates with a low heat capacity, thus keeping the overall power consumption for heating and cooling at a minimum. Moreover, high thermal conductivity provides an efficient heat transfer, prevents the buildup of temperature gradients, and thus allows for a uniform temperature distribution within the substrate. In addition, the temperature uniformity can be

further enhanced by rotating the substrate relative to the beamlets. Also, this rotation allows analyzing multiple qPCR samples by moving them past a miniaturized fluorescence detector. All components in physical contact with the substrate, except the sample and/or sample tubes, should be thermal isolators with low/poor heat capacities.

[0033]. The substrate may be made of the following types of materials: metals, metal alloys, and metal composites (e.g., aluminum, magnesium, and steel), ceramics (e.g. aluminum nitride), thermally conductive polymers (e.g. polypropylene, polycarbonate, polyamides, polyolefin, and liquid crystal polymers), diverse carbon species (e.g. diamond, carbon nanotubes, and carbon fibers/particles), and any combinations thereof (e.g. a gold coated thermally conductive polymer).

[0034]. In one embodiment the substrate is in the form of a band such as a ring. This may take on several forms for example the entire outer surface of the ring may be made matte-black by selective anodic oxidation of a polished aluminum ring using diverse masking techniques (e.g. wax) (see Figure 1A). In this example, the height of the ring correlates with the diameter of the laserdiode light beamlets. Additionally, the holes/slots for accommodating the PCR tubes might be blackened or not.

[0035]. In yet another embodiment the substrate is in the shape of the ring, whereby only a small matte-black band covers the outer surface of the ring (see Figure 1B). This set-up has a smaller matte-black surface area and thus reduced radiation losses and a lower overall power consumption. Here, the diameter of the laserdiode light beamlets can be varied by using different types of collimators/focusers (typically 0.5-5mm beam diameters over a free-space traveling distance of 30-200mm of the laserdiode light). Additionally, the holes/slots for accommodating the PCR tubes might be blackened or not.

[0036]. In yet another embodiment the substrate is in the shape of the ring, whereby only a few matte-black circles cover the outer surface of the ring (see Figure 1C). In terms of electrical/optical input power, this set-up represents one of the most economic solutions and does not require the substrate being rotated.

[0037]. In yet another embodiment the substrate is in the shape of a transparent ring, whereby only the holes/slots accommodating the PCR tubes are blackened (see Figure 1D).

[0038]. In one embodiment the substrate may be formed of a foam. For example a metallic foam

[0039]. In one embodiment the substrate may be in the form of particles within the sample. For example in a colloidal arrangement with particles or photosensitizer within the PCR sample (see Figure 1E). The particles within the sample might be in the form of a solution, suspension, (colloidal) dispersion, or an emulsion. Examples for such substrates might be [but not limited to] quantum dots (e.g. gold particles), magnetic particles, synthetic diamonds, photosensitizers, and any combinations thereof. Besides their role as a substrate, quantum dots, magnetic particles, and photosensitizers could be employed as probes for additional sensing purposes (e.g. a spectral shift in the emission spectrum of a quantum dot could be used as a temperature sensor). Also, a magnetic particle (e.g. silica-coated paramagnetic particles) could be used for a sample preparation preceding the PCR.

[0040]. It is also possible to use the substrate directly as a disposable reaction vessel. Figure 1F shows an illustrative example of a substrate, which is manufactured by co-injection molding of a matte-black thermally conductive polymer (e.g. polypropylene) and a native transparent polypropylene. Here, the transparent bottom or lid will enable optical detection. Besides being low-cost, a disposable substrate also prevents cross-contamination between subsequent qPCR runs—an important aspect in clinical diagnosis of infectious diseases.

[0041]. In yet another embodiment the substrate may be in the form of a metal mesh or metal foam within the PCR sample solution

[0042]. The device includes a laserdiode light source. In one embodiment the device further includes an additional laserdiode light source. Two or more laserdiodes can be operated at different wavelengths, frequencies, phases, or optical output powers. Laserdiode light is also referred to herein as beam(s) or beamlet(s). For routing the laserdiode light to the substrate, different optical components, such as collimators/focusers, beamsplitters (e.g. plate beamsplitters), optical switches, diffractive optics (e.g. 2D gratings or diffusers), mirrors, etc. can be used. One or all of these optical elements can already be an integral part of a laserdiode. One such example would be a laserdiode with an in-built Fresnel lens for beam shaping/collimation (see Figure 2A and 2B). In one embodiment, a beam shaped in the form of an annular ring (e.g. generated by an axicon) can be used, whereby the laserdiode light

might be projected from either above or below the substrate. This set-up would have the advantage, that one optical element alone would be sufficient to provide a substantially homogeneous illumination of the substrate without the build-up of local temperature gradients.

[0043]. In one embodiment the device further comprises one or more optical elements selected from a beam splitter, a diffractive optical element, a mirror, a lens, a light guide or an optical switch is positioned in the path of a light beam between the laser diode and the substrate. There are several formats to optimize the use of optical elements. Any permutations of laser diodes and optical elements should be calculated to heat the substrate substantially uniformly.

[0044]. In one embodiment the device comprises a 1×3 diffractive optical element (DOE) (as an example of a two-dimensional grating to manipulate laserdiode light) in combination with two mirrors (see Figure 3A). Here, the beam of a fiber-pigtailed laserdiode is collimated and split into 3 beamlets of equal intensity (1:1:1), which are equally spaced (120°) along the ring. The beamlet of the 0st order impinges directly upon the ring, whereas the beamlets of the 1st orders are deflected onto the ring by two mirrors. This particular set-up provides a uniform temperature distribution within a stationary (non-rotating) ring. A thermopile temperature sensor in a closed loop is employed for contactless temperature measurements. Various diffraction orders might be used. Also, three-dimensional diffractive optical elements might be employed. Preferably, the split ratio of the beamlets should be equal. However, any split ratios can be employed. Although non-equal split ratios might result in a larger temperature gradient within the ring, the temperature gradient can be easily lowered under $\pm 0.5^\circ\text{C}$ by varying the rotational velocity of the ring. For any given setup, the temperature uniformity can be effectively controlled within $\pm 0.5^\circ\text{C}$ by adjusting four independent parameters: the relative orientation, number, and optical output power of the beamlets, as well as the rotational speed of the ring. Increasing the rotational speed of the ring compensates for an imbalanced power distribution in the beamlets—a feature, which opens up new ways for dispensing the infrared (IR) radiation to the ring (see Figure 3B).
Legend for Figure 3A: C collimator, D 1×3 diffractive optical element (DOE), G glass PCR tube, M1 and M2 mirrors to project split beamlets onto ring, R ring, T thermopile. The design

of the ring shown in Figure 3A is advantageous as it provides a very low thermal mass for a given ring diameter.

[0045]. In yet another embodiment the device comprises an array of 2 plate beamsplitters in combination with three mirrors (see Figure 3C). Here, the beam of a fiber-pigtailed laserdiode is collimated and split into 3 beamlets of equal intensity (1:1:1), which are equally spaced (120°) along the ring. This particular set-up provides a uniform temperature distribution within a stationary (non-rotating) ring. A thermopile temperature sensor in a closed loop is employed for contactless temperature measurements. The number of beamsplitters and mirrors might be varied. Preferably, any combination/permutation involving arrayed beamsplitters should result in beamlets of equal intensity. However, although non-equal split ratios might result in a larger temperature gradient within the ring, the temperature gradient can be easily adjusted by varying the rotational velocity of the ring. Alternatively, a $1 \times N$ fiberoptic beamsplitters can be used (see Figure 3D).

[0046]. In yet another embodiment the device comprises a combination of 4 arrayed beamsplitters, four mirrors, and 4 1×3 diffractive optical elements (see Figure 3E) Here, the beam of a fiber-pigtailed laserdiode is collimated and split into 12 beamlets of equal intensity (1:1:1:1:1:1:1:1:1:1:1:1), which are equally spaced (30°) along the ring. This particular set-up provides a uniform temperature distribution within a stationary (non-rotating) ring. A thermopile temperature sensor in a closed loop is employed for contactless temperature measurements. Alternatively, a diffuser might be used instead of 1×3 diffractive optical element. The number of beamsplitters, mirrors, and diffractive optical elements might be varied. Preferably, any combination/permutation involving arrayed beamsplitters should result in beamlets of equal intensity. However, although non-equal split ratios might result in a larger temperature gradient within the ring, the temperature gradient can be easily adjusted by varying the rotational velocity of the ring.

[0047]. Preferably the device may further comprise a fan or a blower to remove thermal energy from the substrate A fan or a blower may actively vary or control the temperature of the substrate (including PCR tubes and PCR samples). Alternatively, a vortex tube or compressed air might be used.

[0048]. Preferably the device may further comprise a signal processor for detecting a signal of the sample being analyzed. The device sensor may be a fluorescent signal processor connected to a fluorescence detector for processing a fluorescent signal (emerging from the PCR sample in the PCR tube). Alternatively it could be for the detection of electro

[0049]. Preferably the device comprises a portable battery. The laser diode light source used to heat the substrate requires electrical energy for operation. The device is designed to consume less than 10Wh of electrical energy to generate the thermal cycles for denaturation, annealing and extension. Thus the device will be compact and light weight which allows it to be easily portable and field deployable. The device can be used in remote settings and powered by Lithium ion batteries comparable to those used in laptops and notebook computers. The device preferably comprises a small form-factor battery (lithium-ion or lithium polymer-based batteries).

[0050]. In one embodiment the substrate may comprise two or more substrates. This possibility is to use one collimated laserdiode light beam (without placing any other optical elements except at least one mirror between the collimator and the substrate) to project the laserdiode light at multiple substrates (see Figure 10A-C). This is an advantage, because only a limited number of optical elements would be needed to affect heating. A further advantage of this set-up is, that the thermal mass of the samples is more or less identical with the thermal mass of the substrates, which would enable faster heating and cooling (compared to one large substrate with a rather large thermal mass). Also, the substrates would act as disposable reaction containers. E.g. in Figure 10A, 3 rotating disposable black substrates, which are slotted into a substrate holder, are heated simultaneously by one laserdiode light beam. E.g. in Figure 10B, 6 rotating disposable black substrates, which are slotted into a substrate holder, are heated simultaneously by one laserdiode light beam.

[0051]. Instead of a stepper motor, a DC motor or acoustic motors (see Figure 11) might be used. Figure 11 shows an example of a printed circuit board (PCB)-based motor, which uses friction force to rotate the substrate holder. In total 3 black disposable substrates are slotted into the substrate holder, whereby the laserdiode beam is guided as outlined in Figure 10A.

[0052]. The device may further comprise a temperature sensor not in contact with the substrate.

[0053]. The compact size and the low weight of the device make it ideally suited for portability. Among those temperature sensor might be Pt RTD temperature sensors, thermocouples, and non-contact thermal and optical sensors, such as thermopiles, bolometers, or pyrometers.

[0054]. A method for amplifying and/or analyzing a nucleic acid sample is described herein comprising the steps of:

- a. placing the nucleic acid sample in contact with a substrate;
- b. heating the substrate to a first temperature and maintaining the first temperature with a laser diode light source; said light projected on the substrate to absorb the light and convert the light energy to heat energy thereby raising the temperature of the substrate corresponding to the intensity of light energy, the substrate configured to transfer the thermal energy substantially homogenously to the nucleic acid sample;
- c. lowering the temperature of the substrate to a second temperature and maintaining the substrate at the second temperature; and
- d. detecting a fluorescence signal of the nucleic acid sample.

[0055]. Preferably more than one nucleic acid sample is amplified.

[0056]. Preferably the thermal cycle comprises real time polymerase chain reaction to amplify the nucleic acid sample. A detailed method may include the following steps.

- a. associating the nucleic acid sample with the substrate for transfer of thermal energy;
- b. heating the substrate with electromagnetic radiation from a laser diode light source, the substrate configured to absorb the radiation and convert the radiated energy to heat energy thus raising the temperature of the substrate corresponding to the radiated light intensity; and then transfer the heat energy to the nucleic acid sample,

- c. a cooling system such as a fan or a blower to remove thermal energy from the substrate; and then maintaining the temperature of the substrate at this new thermal state by heating the substrate with a lower light intensity from the laser diode;
- d. one thermal cycle consists of a heating and cooling/maintaining phase
- e. thus producing a thermal cycle comprising of at least one heating and cooling cycle and the nucleic acid sample containing at least one nucleic acid which undergoes amplification in response to the thermal cycle;
- f. detecting the fluorescence of the nucleic acid sample.

The method is suitable for amplifying more than one nucleic acid sample.

Preferably the method comprises real time polymerase chain reaction to amplify the nucleic acid sample.

[0057]. The method relies on photonic principles, whereby an excitation light converts the light energy to thermal energy and transfers the thermal energy to a sample.

[0058]. Preferably the method is for amplification of more than one nucleic acid sample. Preferably the method uses real time polymerase chain reaction to amplify the nucleic acid sample. It would be understood that the method described herein may be applied to any nucleic acid amplification methods known in the art.

Preferred Embodiments:

[0059]. The system is able to capture real-time qPCR data using a multiplex-capable fluorescence detector. Presently, up to 4 colors/optical channels (blue, green, orange, and red) in the visible range of the spectrum (VIS) can be addressed simultaneously by placing one or more detectors along the ring perimeter. However, the system is not limited to 4 optical channels and can be upgraded accordingly, e.g. by introducing additional channels in the ultraviolet (UV), VIS, and near infrared range (NIR). Dependent on the systems' configuration, 1-36 samples can be processed at a time. Typically, the working volumes are in the range of 1 to 10uL. If needed, larger volumes can be processed by changing the system accordingly.

[0060]. The systems' mode of operation completely relies on photonic principles: light at different wavelengths, frequencies, and phases is used for heating/cooling, temperature sensing, positional sensing, and optical detection.

[0061]. Figure 4A depicts an example of a set-up. An 8W 808nm-laserdiode light beam is equally split into 3 beamlets using a 1×3 fiberoptic beamsplitter and projected onto a stepper motor-driven matte-black ring holding multiple PCR sample tubes. A thermopile temperature sensor working above 5μm in a feedback loop controls the ring temperature by regulating the laserdiode drive current. In addition to natural convection and/or radiation, a fan allows for active cooling using ambient air. An optical interrupter/flag operating at 980nm moves the black ring –and thus PCR sample tube 1 to its home position above an optical detection system for initiating the real-time fluorescence data acquisition, which is performed by means of incremental step counting in either a stop-and-go or on-the-fly mode. Two-color optical detection (Figure 5A) is monitored between 475 and 655nm. Legend for Figure 4A: A3 aspheric lens of the fluorescence detection system, De two-color optical detection system, Fa cooling fan for active cooling with ambient air, Fi1-3 3 fiberoptic ends of a 1×3 fiberoptic beamsplitter, G PCR glass capillary, I optical interrupter together with optical flag for indexing/mapping of the sample positions, L1 and L2 LEDs used as excitation lightsources in the fluorescence detector, R black ring for absorbing the laserdiode light guided by the fiberoptics, St stepper motor to rotate the ring, T thermopile temperature sensor for controlling the ring temperature, W wheel for coupling the ring to the motor shaft. The bar size is 10mm. The interrupter might be replaced by an absolute or incremental encoder.

[0062]. Figure 4B depicts yet another set-up, in which a collimated light beam of a 10W 980nm-laserdiode is collimated, equally (1:1:1:1) split into 4 beamlets using an array of plate beamsplitters and mirrors and projected onto a stepper motor-driven matte-black ring holding multiple PCR sample tubes. The split ratio of all three beamsplitters is 50:50 (transmission/reflection), i.e. all 4 beamlets impinging on the black ring carry 25% of the original intensity. Legend for Figure 4B: A3 aspheric lens of the fluorescence detection system, BS 50:50 plate beamsplitter, C fiberpigtailed collimator for collimating or focusing the laserdiode light, De two-color optical detection system, Fa cooling fan for active cooling with ambient air, G PCR glass capillary, M 45°-mirror to project the beamlets onto the ring,

R black ring for absorbing the laserdiode light guided by the fiberoptics, St stepper motor to rotate the ring, T thermopile temperature sensor for controlling the ring temperature, W wheel for coupling the ring to the motor shaft. It is understood that other types of optical arrangements might be used instead, e.g. a monolithic approach, in which beamsplitters and mirrors are fused into one optical element. Also, beamsplitters with different split ratios, coatings, and incident angles might be combined. Moreover, mirrors having different coatings and incident angles might be combined. Using various permutations, the thermal management of the device might be accomplished with laserdiodes operating at different wavelengths and/or intensities.

[0063]. A matte-black black anodized aluminum ring is used as the substrate holder to absorb infrared radiation from the beamlets (see Figures 1A-E). The absorbed heat is transferred by conduction and/or radiation to the PCR sample tubes held at locations around the substrate holder. The combination of a black anodized aluminum ring in combination with polypropylene (PP)-overmolded glass or plastic PCR sample tube, and polyether ether ketone (PEEK) wheel yields temperature transition rates of more than $\pm 10^{\circ}\text{C/s}$ (see Figure 4C) and an average power consumption of around 4W (see Figure 4D). Besides aluminum, other thermally conductive materials, such as metals, metal alloys, and metal composites, ceramics, thermally conductive polymers, diverse carbon species, and any combinations thereof can be used. Due to its low specific weight matte-black anodized magnesium is preferable.

[0064]. In one embodiment, the entire ring is matte-black. A matte-black surface can be generated by various techniques, such as anodization methods, electrochemical plating, electroless deposition, spray painting, carbonization, incorporation of carbon fibers, incorporation of photosensitizers, etc. A matte-black surface is preferred because it acts like a black body, thereby absorbing all incident electromagnetic radiation over a wide wavelength range.

[0065]. In another embodiment, the ring surface has an emissivity value of larger than 0.9. In yet another embodiment, only those segments of the ring, on which the infrared (IR) radiation impinges, are blackened (e.g. with a coating having an emissivity value of larger than 0.9). In yet another preferred embodiment, the ring coating has an emissivity value

substantially equals to 1. The other portions are not blackened or coated in order to minimize radiation losses, which might contribute as much as 30%. Preferable those non-blackened portions should have an emissivity of less than 0.9 (see Figures 1A-E). In addition to IR, other wavelengths of the electromagnetic spectrum, such as ultraviolet (UV) or visible (VIS) can be utilized.

[0066]. The two-channel fluorescence detector is based on a miniature optical bench populated with common (electro)optical components (see Figure 5A). Utilizing low-cost LEDs, antireflective (AR)-coated aspheric lenses, a hermetically-sealed silicon (Si) photodiode, as well as hardcoated filters does not require any maintenance or calibration during the entire lifecycle of the device. Unlike to an off-axis orientation, the in-axis configuration of the excitation and emission beam pathways adds more flexibility with respect to the PCR sample tube position and geometry. Moreover, each LED is individually modulated, which makes it possible to simultaneously monitor both optical channels under ambient light. Figure 5A shows a side view of two-color optical detection system. Legend for Figure 5A: A1 and A2 aspheric lenses for collimating LED excitation light, A3 aspheric lens for focusing excitation light into the PCR sample tubes and collimating fluorescence light from the PCR sample tubes onto the photodetector (see Figure 4A and B), Di dualband dichroic mirror, Em dualband emission filter, Ex1 and Ex2 excitation filters, Fa fan for active cooling with ambient air, Fi1-3 1×3 fiberoptic beamsplitter adapters, G glass PCR tube, Li lighttrap for minimizing stray light being backscattered from the dichroic mirror, Lo longpass filter, P Si photodiode, R matte-black ring, Sh stepper motor shaft, St stepper motor, T thermopile temperature sensor, W wheel for coupling the ring to the stepper motor shaft. Bar size is 10mm. In another embodiment, a bolometer or pyrometer might be used for temperature control. Despite employing only standard microscopy fluorescence filter sets and using less than 5 μ L qPCR reaction volumes, the device rivals any thermocycler in the market with limits of detection (LODs) of less than 1nM for most fluorogenic probes popular in qPCR (see Figure 5B).

[0067]. So far, the system has been evaluated with clinical samples using World Health Organisation standards in qPCR applications targeting infectious diseases, such as influenza (see Figure 6A), HIV-1 (see Figure 6B), tuberculosis (see Figure 6C), and hepatitis (data not

shown). We have run feasibility studies with blood samples using the smart amplification process (SMAP) aiming at companion diagnostics, for example warfarin (data not shown). Unlike PCR, SMAP is an isothermal amplification process performed at 60°C, in which the denaturation step is enzymatically effected. Consequently, only around 1.4W average power consumption is required, which is why isothermal amplification formats are an attractive choice for decentralized diagnostic tests using our device.

[0068]. Laserdiodes used so far ranged from under 400nm (UV) to more than 2300nm.

[0069]. Figure 7A depicts a melt curve analysis for the H5 target (black) and a no-template control (red).

[0070]. The low power consumption combined with a weight of less than 2kg and small DIN A5-form factor make it possible to run the device with a standard Li-ion 12-cell 98Wh laptop battery for a whole working day in the field.

[0071]. In a further embodiment, the device/system contains additional components, such as a display, global positioning system (GPS), battery/recharging circuit, wireless local area network (WLAN), interlock system(s) to protect the user from radiation hazards during operation, a beam shutter, absolute or incremental position encoders, MCU/embedded PC, controller(s), and software for each of those; and a power source for powering said device.

[0072]. Figure 8A shows the correlation of the qPCR sample temperature measured by a Pt1000 resistive temperature device (RTD) sensor and a thermopile, which was calibrated for temperatures between room temperature and 100°C.

[0073]. Figure 8B depicts one full thermocycle (5s at 95°C, 5s at 60°C, and 5s at 72°C), whereby the temperature was monitored using a thermopile. Black indicates the object temperature and blue the reference temperature within the thermopile.

[0074]. The comparison of an entirely black ring and a partially black ring (see Figure 8C) demonstrates, that radiation losses are lowered by using a partially blackened ring (inside and holes/slots have been protected during the black anodization process). Here, the partially blackened ring reaches 95°C in a shorter time (see Figure 8C).

[0075]. Heating using paramagnetic particles, in which the 'substrate' is suspended into the qPCR solution (see Figure 1E). Surprisingly, the temperature was stable up to around

130°C. This feature allows setting the target temperature way above 100°C and thus enabling faster ramp/heating rates. In addition, this mode of heating would be independent of any vibrational features of water i.e. this mode of heating is wavelength-independent and allows to pick a laserdiode based solely on its efficiency and cost (see Figure 9). At the same time, the paramagnetic particles could be used for the sample preparation process, which proceeds the qPCR.

Preferred Embodiments

Example 1

[0076]. In one embodiment, the invention is a thermal system for amplification of a nucleic acid sample comprising:

- an electromagnetic radiation emitted from a laser diode light source;
- an optics manipulation system that splits the light beam from the laser diode and generates spatially distributed multiple light beamlets using optic fibres, collimators/focusers, plate beam splitters, diffraction gratings and mirrors
- a substrate positioned in a path of above said light beamlets and configured to absorb the radiated light energy and generate heat energy ;
- a holding device (reaction compartment) to hold said nucleic acid sample, said holding device in physical contact with the substrate, said holding device configured to transmit the heat from the substrate to the nucleic acid sample; and
- the nucleic acid sample containing at least one nucleic acid which undergoes amplification in response to the thermal cycle
- a cooling system to cool said substrate and samples to a different temperature setting
- Platinum RTD sensors, thermocouples and non-contact thermopile sensors to accurately measure the temperature of the substrate and samples,
- A feedback PID control system for the above said thermal management and to produce thermal cycles required for nucleic acid processing such as 95⁰C for denaturation and 60⁰C for annealing/extension for example.
- the nucleic acid sample containing at least one nucleic acid which undergoes amplification in response to the thermal cycle

Example 2

[0077]. The thermal system of Embodiment in Example1 for amplification of nucleic acid samples further comprising:

- additional holding devices (=reaction compartments) to hold additional nucleic acid samples;
- additional electromagnetic radiation laser diode light sources;
- the above mentioned nucleic acid sample of Embodiment 1 and the addition of nucleic acid samples placed in physical contact with the substrate and spaced apart and thermally communicating with one another via the said substrate; and

the substrate configured to rotate so that separate nucleic acid samples are positioned in a path of radiated light from each electromagnetic source at a time and each thermal cycle experienced by each nucleic acid sample is identical.

Example 3

[0078]. A thermocycler device comprising:

- a detection system;
- a fluorescent signal processor connected to said detection system for processing a fluorescent signal detected by said detection system;
- a thermal system as defined in Embodiment Example1 or Embodiment Example2 above;
- optional components such as display, GPS, battery/recharging circuit, WiFi, optical position sensor for detection system, MCU/embedded PC, controller(s) and software for each of those; and
- a power source for powering said device.

[0079]. The device is designed to be used with a Software that: a) interfaces, qPCR data manipulation at the end of the run, log service (GPS), real-time data streaming (WiFi/GSM in combination with dedicated server), healthcare services, GMP compliance, minimum requirement for scientific publications, remote diagnosis function.

[0080]. Those skilled in the art will appreciate that the invention described herein is susceptible to variations and modifications other than those specifically described. The invention includes all such variation and modifications. The invention also includes all of

the steps, features, formulations and compounds referred to or indicated in the specification, individually or collectively and any and all combinations or any two or more of the steps or features.

[0081]. Each document, reference, patent application or patent cited in this text is expressly incorporated herein in their entirety by reference, which means that it should be read and considered by the reader as part of this text. That the document, reference, patent application or patent cited in this text is not repeated in this text is merely for reasons of conciseness.

[0082]. Any manufacturer's instructions, descriptions, product specifications, and product sheets for any products mentioned herein or in any document incorporated by reference herein, are hereby incorporated herein by reference, and may be employed in the practice of the invention.

[0083]. The present invention is not to be limited in scope by any of the specific embodiments described herein. These embodiments are intended for the purpose of exemplification only. Functionally equivalent products, formulations and methods are clearly within the scope of the invention as described herein.

[0084]. The invention described herein may include one or more range of values (eg size, concentration etc). A range of values will be understood to include all values within the range, including the values defining the range, and values adjacent to the range which lead to the same or substantially the same outcome as the values immediately adjacent to that value which defines the boundary to the range.

[0085]. Throughout this specification, unless the context requires otherwise, the word "comprise" or variations such as "comprises" or "comprising", will be understood to imply the inclusion of a stated integer or group of integers but not the exclusion of any other integer or group of integers. It is also noted that in this disclosure and particularly in the claims and/or paragraphs, terms such as "comprises", "comprised", "comprising" and the like can have the meaning attributed to it in U.S. Patent law; e.g., they can mean "includes", "included", "including", and the like; and that terms such as "consisting essentially of" and "consists essentially of" have the meaning ascribed to them in U.S. Patent law, e.g., they

allow for elements not explicitly recited, but exclude elements that are found in the prior art or that affect a basic or novel characteristic of the invention.

[0086]. Other definitions for selected terms used herein may be found within the detailed description of the invention and apply throughout. Unless otherwise defined, all other scientific and technical terms used herein have the same meaning as commonly understood to one of ordinary skill in the art to which the invention belongs.

[0087]. While the invention has been described with reference to specific methods and embodiments, it will be appreciated that various modifications and changes may be made without departing from the invention.

Claims:

1. A method for adjusting the temperature of a sample, the method comprising the steps of:
 - a. Heating a substrate with a laser diode light; said light projected on to the substrate to absorb the light and convert the light energy to thermal energy thereby raising the temperature of the substrate corresponding to the intensity of the light energy; and
 - b. Rotating the substrate to transfer the thermal energy substantially homogenously to the sample,

wherein a portion of the substrate that comes into contact with the light has an emissivity value of larger than 0.9.
2. The method of claim 1 wherein the portion of the substrate that comes into contact with the light has an emissivity value substantially equal to 1.0.
3. The method of claim 2 wherein the portion of the substrate that comes into contact with the light is black.
4. The method of claim 1 wherein a portion of the substrate that does not come into contact with the light has an emissivity value less than 0.9.
5. The method of claim 4 wherein the portion of the substrate that does not come into contact with the light is non-black.
6. The method of any one of claims 1 to 5 further comprising the step of;

Removing the light energy from the substrate to lower its temperature and maintaining the substrate to a new temperature.
7. The method of claim 6 further comprising the step of actively cooling the substrate.
8. The method of any one of claims 1 to 7 further comprising the step of;

detecting the temperature of the substrate via a sensor not in contact with the substrate
9. The method of any one of claims 1 to 8 further comprising the step of detecting a signal from the sample via a sensor.

10. The method of any one of claims 1 to 9 wherein the sample is a nucleic acid sample.
11. The method of any one of claims 1 to 10 further comprising of two or more laser diode light sources.
12. The method of any one of claims 1 to 11 further comprising the step of optical manipulation of the light by focusing, collimating, splitting, diffracting, switching or reflecting to generate multiple beamlets spatially distributed and directed on to the substrate .
13. A device for adjusting the temperature of a sample, the device comprising: a laser diode for projecting a light to a substrate; said light adapted to be projected substantially homogeneously on to the substrate to absorb and convert the light energy to thermal energy thereby raising the temperature of the substrate corresponding to the intensity of the light energy, wherein the substrate is configured to rotate to transfer the thermal energy substantially homogeneously to the sample and wherein a portion of the substrate that comes into contact with the light has an emissivity value of larger than 0.9.
14. The device of claim 13 wherein the portion of the substrate that comes into contact with the light has an emissivity value substantially equal to 1.0.
15. The device of claim 14 wherein the portion of the substrate that comes into contact with the light is black.
16. The device of claim 13 wherein a portion of the substrate that does not come into contact with the light has an emissivity value less than 0.9.
17. The device of claim 16 wherein the portion of the substrate that does not come into contact with the light is non-black.
18. The device of any one of claims 13 to 17 wherein the substrate is in the form of a band.
19. The device of any one of claims 13 to 17 wherein the substrate is in the form of a foam.
20. The device of any one of claims 13 to 19 wherein the substrate is made of metals, alloys, metal composites or polymers.
21. The device of any one of claims 13 to 17 wherein the substrate is in the form of particles within the sample.

22. The device of claim 21 wherein the particles comprise a quantum dot.
23. The device of claim 21 wherein the particles comprise a magnetic particle.
24. The device of claim 21 wherein the particles comprise a photosensitizer.
25. The device of any one of claims 13 to 24 further comprising one or more optical elements selected from a beam splitter, a diffractive optical element, a mirror, a lens, a light guide or an optical switch is positioned in the path of a light beam between the laser diode and the substrate.
26. The device of any one of claims 13 to 25 further comprising a fan or a blower to remove thermal energy from the substrate.
27. The device of claim 13 further comprising a signal processor for detecting a signal of the sample being analyzed.
28. The device of any one of claims 13 to 27 further comprising a portable battery.
29. The device of any one of claims 13 to 28 wherein the substrate comprises two or more substrates.
30. The device of any one of claims 13 to 29 further comprising a temperature sensor not in contact with the substrate.
31. A method for amplifying and/or analyzing a nucleic acid sample, the method comprising the steps of:
 - a. placing the nucleic acid sample in contact with a substrate;
 - b. heating the substrate to a first temperature and maintaining the first temperature with a laser diode light source; said light projected on the substrate to absorb the light and convert the light energy to thermal energy thereby raising the temperature of the substrate corresponding to the intensity of light energy;
 - c. rotating the substrate to transfer the thermal energy substantially homogenously to the nucleic acid sample;
 - d. lowering the temperature of the substrate to a second temperature and maintaining the substrate at the second temperature; and

- e. detecting a fluorescence signal of the nucleic acid sample,
wherein a portion of the substrate that comes into contact with the light has an emissivity value of larger than 0.9.
- 32. The method of claim 31 wherein the portion of the substrate that comes into contact with the light has an emissivity value substantially equal to 1.0.
- 33. The method of claim 31 wherein a portion of the substrate that does not come into contact with the light has an emissivity value less than 0.9.
- 34. The method of claim 31 wherein more than one nucleic acid sample is amplified.
- 35. The method of claim 31 wherein the thermal cycle comprises real time polymerase chain reaction to amplify the nucleic acid sample.
