

Description

This invention relates to methods for optimizing sootblowing in boilers, for instance fossil fuel boilers.

The combustion of fossil fuels, for the production of steam or power, generates a residue broadly known as ash. All but a few fuels have solid residues and, in some instances, the quantity is considerable.

For continuous operation, removal of ash is essential. In suspension firing the ash particles are carried out of the boiler furnace by the gas stream and form deposits on tubes in the gas passes (fouling). Under some circumstances, the deposits may lead to corrosion of these surfaces.

Some means must be provided to remove the ash from the boiler surfaces, since ash in its various forms may seriously interfere with operation or even cause shut-down. Furnace wall and convection-pass surfaces can be cleaned of ash and slag while in operation by the use of sootblowers using steam or air as a blowing medium. The sootblowing equipment directs product air through retractable nozzles aimed at the areas where deposits accumulate. The convection-pass surfaces in the boiler, sometimes referred to as heat traps, are divided into distinct sections in the boiler, e.g. superheater, reheater and economizer sections. Each heat trap normally has its own dedicated set of sootblowing equipment. Usually, only one set of sootblowers is operated at any time, since the sootblowing operation consumes product steam and at the same time reduces the heat transfer rate of the heat trap being cleaned.

Scheduling and sequencing of sootblowing is usually implemented with timers. The timing schedule is developed during initial operation and startup of the boiler. In addition to timers, critical operating parameters, such as "gas side" differential pressure, will interrupt the timing schedule when emergency plugging or fouling conditions are detected. The expression "gas side" used herein, means the side of a heat trap which is in contact with exhaust gas.

The sequencing, scheduling and optimizing of the sootblowing operations can be automated by using controls, such as shown in our published European Patent Application No. EP—A—0 101 226, entitled Sootblowing Optimization.

The scheduling is usually set by boiler cleaning experts who observe boiler operating conditions and review fuel analyses and previous laboratory tests of fuel fouling. The sootblower schedule control settings may be accurate for the given operating conditions which were observed, but the combustion process is highly variable. There are constant and seasonal changes in load demand and gradual long term changes in burner efficiency and heat exchange surface cleanliness after sootblowing. Fuel properties can also vary for fuels such as bark, refuse, blast furnace gas, residue oils, waste sludge, or blends of coals. As a result, sootblowing scheduling based on several days of operating cycles may not result in the most economical or effective operation of the boiler. Present practice for sootblowing scheduling is based on the use of timers. The timing schedule is developed during initial operation and start-up, and according to the above application, can be economically optimized for constant and seasonal changes in load demand, fuel variations, and gradual long term changes in burner efficiency and heat exchange surface cleanliness after sootblowing.

A boiler diagnostic package which can be used for sootblowing optimization has been proposed by T. C. Heil *et al* in an article entitled "Boiler Heat Transfer Model for Operator Diagnostic Information" given at the ASME/IEEE Power Gen. Conference in October 1981 at St. Louis, Missouri, USA. The method depends upon estimates of gas side temperatures from coupled energy balances, and the implementation requires extensive recursive computations to solve a series of heat trap equations.

As noted, various approaches have been developed to optimize the use of sootblowing equipment. One method proposed by the Babcock & Wilcox Company computes optimum sootblowing schedules using a model of boiler fouling characteristics which is adapted on-line. An identification of the rate of total boiler efficiency versus time ("fouling rate") is computed for multiple groupings of sootblowers in the various heat traps, of sootblowers using only a measure of relative boiler efficiency. Using this information, the economic optimum cycle times for sootblower operation are predicted.

For the above scheme and others similar to it, a critical part of the computation is the identification of the "fouling rates". A major problem in this identification is the interaction of the effects due to multiple heat trap operations. Some methods have assumed these effects to be negligible in their scheme, while other methods require a large number of additional inputs attempting to account for these interactions. For some combustion units with sootblowers, neglecting multiple heat trap interactions is valid (i.e., utility boilers). However, for many units sootblowing is a continuous procedure and a method of accounting for the interactions is necessary. This method should be implemented without adding a large number of expensive inputs.

Our above-cited published European Patent Application No. EP—A—0 101 226, being filed on 13.07.84 and having the priority date 14.07.83, discloses a method of optimizing a sootblowing operation in a boiler having a plurality of heat traps lying in series along a gas flow path, comprising:

calculating an optimum time between sootblowing operations of each heat trap based on scaling parameters and a cost factor for the sootblowing operation;

obtaining a difference value between a set time between sootblowing operations and the optimum time between sootblowing operations of each heat trap and comparing the difference value for each heat trap with a selected value which is indicative of the desirability for initiating a sootblowing operation for each heat trap; and

initiating the sootblowing operation only in the heat trap having the lowest difference value between heat traps indicated as desirable for initiating a sootblowing operation.

By virtue of EPC Article 54(3), EP—A—0 101 226 forms part of the state of the art as regards the present application for the purposes of novelty only.

5 According to the invention there is provided a method of optimizing a sootblowing operation in a boiler having a plurality of heat traps lying in series along a gas flow path, comprising:

calculating an optimum time between sootblowing operations of each heat trap based on scaling parameters and a cost factor for the sootblowing operation;

10 obtaining a difference value between a set time between sootblowing operations and the optimum time between sootblowing operations of each heat trap and comparing the difference value for each heat trap with a selected value which is indicative of the desirability for initiating a sootblowing operation for each heat trap;

with the difference value equalling the selected value for only one heat trap, initiating sootblowing in that one heat trap; and

15 with the difference value approaching the selected value for more than one heat trap, delaying the initiation of sootblowing in a downstream one of the heat traps to permit the difference value to equal the selected value in an upstream one of the heat traps to initiate sootblowing in the upstream one of the heat traps before the initiation of sootblowing in a downstream one of the heat traps.

Embodiments of the invention can be used to improve upon the sootblowing optimization of our 20 above-identified published European Patent Application No. EP—A—0 101 226 by initiating sootblowing operations, wherever possible, in an upstream one of the heat traps, so that a heat trap which has just undergone cleansing by sootblowing is not fouled by soot blown off an upstream heat trap when the upstream heat trap undergoes sootblowing.

The expression "boiler", as used herein, includes not only items usually referred to as such, but also 25 other convection heat transfer devices having a plurality of heat traps.

The invention will now be further described, by way of illustrative and non-limiting example, with reference to the accompanying drawings, in which:

Figure 1 is a graph (linearized) showing loss of efficiency due to fouling plotted against time and illustrating the effect of a sootblowing operation on a single heat trap of a boiler;

30 Figure 2 is a graph (linearized) showing the change in overall boiler efficiency plotted against time during fouling and sootblowing operations in a single heat trap;

Figure 3 is a graph (linearized) showing boiler efficiency plotted against time for two separate heat traps;

35 Figure 4 is a graph (linearized) showing the overall efficiency of the boiler of Figure 3 which includes two heat traps;

Figure 5 is a graph plotting loss of efficiency against time for three heat traps in a boiler; and

Figure 6 is a block diagram illustrating how an optimizing scheme for optimizing sootblowing can be improved in a method embodying the invention by selecting an upstream heat trap for sootblowing when 40 more than one heat traps are candidates for sootblowing at the same time.

A method of calculating or identifying parameters of multiple models for the rate of loss of total boiler efficiency due to cleaning of individual heat traps of the boiler by a sootblowing operation will now be described with reference to the drawings.

In a boiler (not illustrated) a plurality of heat traps are usually provided. The heat traps lie in series with respect to a flow of combustion gases. For example, immediately above a combustion chamber, platens 45 are provided which are followed, in the flow direction of the combustion gases, by a secondary superheater, a reheater, a primary superheater and an economizer. Continuing in the flow direction, the flow gases are then processed for pollution control and discharged from a stack or the like.

Each heat trap is provided with its own sootblowing equipment so that the heat traps can be cleaned by 50 sootblowing at spaced times while the boiler continues to operate. Each sootblowing operation, however, has an adverse effect on the overall efficiency of the boiler, during the sootblowing operation proper. The sootblowing operation, by reducing fouling, ultimately increases the efficiency of the particular heat trap being serviced.

As shown in Fig. 1, a fouling rate model can be established which shows the loss of efficiency over a period of time after a sootblowing operation, as the heat trap becomes fouled. The symbol θ_0 is the time 55 since the sootblower last ran in a boiler having only a single heat trap. The time θ_0 is the time during which the sootblowing operation takes place. The loss of efficiency since the last sootblowing operation is a function of time as is the change in efficiency (increase) during the sootblowing operation. These functions for these two periods can be written as follows:

$$60 \quad f_1(t) = a_1 \theta_0^N$$

$$f_2(t) = -b_1 \theta_0^N$$

where a_1 and b_1 are model parameters and N = a coefficient for the fouling rate model.

65 This coefficient and the model itself can be of the type discussed in the Heil *et al*/ article cited above.

While these functions are illustrated as being linear, they need not be so.

For a boiler having only one heat trap, the identification of the adjustable model variable a_1 is easily done. By simply measuring the change in total boiler efficiency due to sootblowing, the model can be evaluated as shown in Fig. 2 and in accordance with the relationship:

$$a_1 = - \frac{\Delta E_1}{E \theta_b^N}$$

where ΔE_1 is the change of overall boiler efficiency due to a sootblowing operation and E is the overall boiler efficiency since the beginning of the last sootblowing operation.

For systems with multiple heat traps, however, the identification of the various parameters a_i for the various heat traps in the models become difficult. One known method assumes, for a system in which the time for sootblowing is much less than times at which no sootblowing takes place, that the identification method can be the same as for a single heat trap. For systems in which this is not the case, however, a more involved calculation must be used.

Fig. 3 illustrates the case where two heat traps are provided and shows the effect of boiler efficiency due to these two traps separately. From outside the boiler however, where the overall efficiency is measured, a composite curve is observed as illustrated in Fig. 4. The parameters a_i for the i^{th} heat trap, in the model, can be calculated from measuring this change and overall efficiency. The relationships for two heat traps with linear fouling models can be written:

$$-\Delta E_1/E = a_1 \theta_{b1} - a_2 \theta_{o1}$$

$$-\Delta E_2/E = a_2 \theta_{b2} - a_1 \theta_{o2}$$

where ΔE_2 is the change in efficiency due to sootblowing in the second heat trap, θ_{o2} is the time for sootblowing in the second heat trap and θ_{b2} is the time since the last sootblowing in the second heat trap.

These various periods of time are illustrated in Fig. 4.

It is noted that the parameter a_2 is negative which implies the cleaning of the second heat trap leads to a decrease in boiler efficiency. In reality, the decrease in boiler efficiency due to the fouling of the first heat trap offsets the cleaning of the second heat trap.

A fouling model for a boiler having three heat traps is illustrated in Fig. 5. The above analysis can be expanded and generalized by any number of heat traps with variable model types and m heat traps as follows:

$$-\Delta E_i/E = a_i \theta_{bi}^{N_i} - \sum_{\substack{j=1 \\ j \neq i}}^m a_j ((T_j + \theta_{oi})^{N_j} - T_j^{N_j})$$

where ΔE_i is the change in efficiency due to sootblowing in the i^{th} heat trap and j is not equal to i (that is, a heat trap other than the heat trap for which the parameters a_i is being calculated) and T_j is the time since sootblowing in the j^{th} heat trap.

For three traps therefore as shown in Fig. 5, the equation for the first heat trap becomes:

$$-\Delta E_1/E = a_1 \theta_{b1}^{N_1} - ((T_2 + \theta_{o1})^{N_2} - T_2^{N_2}) a_2 - ((T_3 + \theta_{o1})^{N_3} - T_3^{N_3}) a_3$$

The method embodying the invention can be implemented using the Network 90[®] as a microprocessor for effecting the various required steps and manipulations.

According to our above-identified European Patent Application Publication No. EP-A-0 101 226, a set value for the time θ_b between sootblowing operations is compared to an optimum value θ_{opt} . The optimum cycle value θ_{opt} is attained as a function, not only of fouling and lost efficiency, but also a cost factor for the sootblowing operation. While the optimum cycle time cannot be calculated directly, a formula is provided which can be utilized to determine the optimum cycle time using conventional trial and error techniques such as Regula-Falsi or Newton-Raphson. The formula for obtaining the optimum cycle time is as follows:

$$O = P \ln \left[\frac{P + \theta_{opt}}{P} \right] - \frac{P(\theta_{opt} + \theta_o)}{\theta_{opt} + P} - \frac{S}{K} + \theta_o$$

where θ_o is the actual sootblowing time, S is the cost of steam for sootblowing and K and P are scaling parameters, K being a function of flow rate of fluid in the boiler and P being a function of K , and incremental steam cost and the cycle time between sootblowing operations.

According to the above-identified published European Patent Application, three conditions were to be met before sootblowing operation in one of a plurality of heat traps was initiated. These conditions were:

- (a) no other sootblower is currently active;
- (b) the difference value between set and optimum cycle time ($\theta_b - \theta_{opt}$) is sufficiently low; and
- (c) if condition (b) exists for more than one heat trap, the heat trap having the lowest difference value is chosen.

According to the present method, a fourth condition is added as follows:

(d) if condition (c) exists, a sootblowing operation for a downstream one of the heat traps is delayed until an upstream one of the heat traps undergoes sootblowing.

By observing this fourth condition, a newly-cleaned downstream heat trap is not prematurely fouled by ash blown from an upstream heat trap.

Referring to Fig. 6, the set and optimum cycle values θ_b and θ_{opt} from four heat traps, numbered 1 to 4, are shown. Comparators 80 to 83 obtain a difference between the optimum and set cycle times, with comparator 84 choosing the smallest difference.

Comparators 86 to 89 as well as low limit detectors 90 through 97 are utilized. AND gates 98 to 101 compare Boolean logic signals and only the AND gate with all positive inputs is activated to operate its respective sootblowing equipment which is connected to control elements 102 to 105 respectively. Sensing unit 110 establishes condition (a) by sensing whether any other blower is currently active. If no other blower is active, an ON or one signal is provided to one of the three inputs of the AND gates 98 to 101.

Condition (b) is established by low limit detectors 90 to 93 with condition (c) being established by low limit detectors 94 to 97.

In Fig. 6, the heat trap designated 1 is considered the upstream most heat trap with the heat traps following in sequence to the last or downstream heat trap 4.

Additional low limit detectors 106, 107 and 108 are connected to the output lines of the first, second, and third heat traps an through OR gates 111 and 112 to transfer units 114 and 115.

An additional transfer units 113 is connected to the output of low limit detector 106. In this manner, if all but the upstream most heat trap (1) is to have sootblowing initiated, its operation is delayed until an upstream one of the heat traps undergoes sootblowing, when that uppermost heat trap is sufficiently near its sootblowing time. Thus condition (d) is established and a freshly cleaned heat trap is not prematurely fouled by ash blown off an upstream heat trap.

Claims

1. A method of optimizing a sootblowing operation in a boiler having a plurality of heat traps lying in series along a gas flow path, comprising:

calculating an optimum time (θ_{opt}) between sootblowing operations of each heat trap based on scaling parameters and a cost factor for the sootblowing operation;

obtaining (in 80, 81, 82, 83) a difference value between a set time (θ_b) between sootblowing operations and the optimum time (θ_{opt}) between sootblowing operations of each heat trap and comparing the difference value for each heat trap with a selected value which is indicative of the desirability for initiating a sootblowing operation for each heat trap;

with the difference value equalling the selected value for only one heat trap, initiating sootblowing in that one heat trap; and

with the difference value approaching the selected value for more than one heat trap, delaying (in 113, 114, 115) the initiation of sootblowing in a downstream one of the heat traps to permit the difference value to equal the selected value in an upstream one of the heat traps to initiate sootblowing in the upstream one of the heat traps before the initiation of sootblowing in a downstream one of the heat traps.

2. A method according to claim 1, including initiating sootblowing in a heat trap only when sootblowing is not taking place in any other heat trap.
