

DESCRIPTION

A SINGLE CARRIER/DS-CDMA PACKET
TRANSMISSION METHOD, AN UPLINK PACKET TRANSMISSION
METHOD IN A MULTI-CARRIER/DS-CDMA MOBILE
5 COMMUNICATIONS SYSTEM, AND A STRUCTURE OF A DOWNLINK
CHANNEL IN A MULTI-CARRIER/DS-CDMA MOBILE
COMMUNICATIONS SYSTEM.

TECHNICAL FIELD

10 The present invention relates to DS-CDMA
(Direct Sequence-Code Divisional Multiple Access)
mobile communications, and particularly relates to
single carrier/DS-CDMA mobile communications and
multi-carrier/DS-CDMA mobile communications.

15

BACKGROUND TECHNOLOGY

Multi-carrier/DS-CDMA mobile
communications and single carrier/DS-CDMA mobile
communications are used as DS-CDMA mobile
20 communications.

When data length to be transmitted is far
longer than one packet length in a single
carrier/DS-CDMA uplink packet transmission method,
an efficient transmission is achieved at the time of
25 call connection by fixedly assigning spreading codes
and time slots to be used in communication.

In this case, efficient multiplexing is
necessary with respect to reservation demand packets
for reserving the allocation of spreading codes and
30 time slots as well as with respect to data packets
for transmitting real data. Since the probability
of reservation demand packets being able to be
transmitted are not controlled in the conventional

technique, collision of reservation demand packets occur frequently at the time of heavy traffic, giving rise to a problem that a transmission efficiency decreases.

5 In "Performance of orthogonal CDMA codes for quasi-synchronous communication systems" (V. DaSilva, E. Sousa: Proc. of ICUPC' vol. 2, pp995-999, 1993), first study was made about the multi-carrier/DS-CDMA method.

10 Unlike the single carrier/DS-CDMA, which transmits a CDMA signal on one carrier, the multi-carrier/DS-CDMA divides a radio-transmission bandwidth, and performs parallel transmission of a CDMA signal by two or more subcarriers.

15 With this provision, the speed of information transmission per subcarrier becomes low, and the speed of code spreading at which information signals are spread to generate CDMA signals also becomes low. Consequently, a chip length of the
20 spreading code can be made longer in the multi-carrier/DS-CDMA than in the single carrier/DS-CDMA. As the chip length is increased, the influence of synchronization errors between spreading codes will be alleviated. Utilizing this feature, the above-
25 mentioned paper applies the multi-carrier/DS-CDMA to communications from mobile stations to base stations in mobile communications systems, and presents a method of performing quasi-synchronous transmission.

 Further, a performance evaluation has been
30 conducted on a link level of the multi-carrier/DS-CDMA.

 "On the Performance of Multi-carrier DS CDMA Systems" (S. Kondo and L. B. Milstein: IEEE

Transactions on Communications, vol.44, no.2,
pp.238-246, February 1996) demonstrates that the
multi-carrier/DS-CDMA provides better properties
than the single carrier/DS-CDMA according to a
5 performance evaluation that is conducted in the
presence of narrow-band interference.

However, conventional studies about the
multi-carrier/DS-CDMA method have been centered
around performance evaluations on the link level,
10 and few studies have been made on how a mobile
station should communicate with a base station and
how a control signal therefor should be transmitted
when this method is applied to a mobile
communication system.

15 Furthermore, these studies have a problem
in that they have been based on the circuit
switching method which always secures a
communication channel of exclusive use from the
start of transmission to its end for signal
20 transmission from a transmitter to a receiver as
usually used in the conventional mobile
communication system.

Moreover, digital mobile communication
systems (for example, a PDC system, a GSM system,
25 and the like) are focused onto voice communication
services, and the systems are designed on the basis
of the circuit switching at present. Further,
although a packet transmission service is planned
also in the next-generation mobile communication
30 system (for example, IMT-2000), which will be
introduced soon, the system design is also based on
the circuit switching. Thus, in a radio-transmission
system based on the circuit switching, channels for

an uplink and a downlink are almost equal in number, and even if a data communication is performed, a symmetrical channel structure of the uplink and the downlink is used. For this reason, transmission of a control command to each user is performed using the channel corresponding to each user.

Conversely, in multimedia mobile communications for which demand is supposed to grow in the future, communications are asymmetrical between the uplink and the downlink. Accordingly, it is conceivable that downlink traffic accounts for most of the traffic when data is downloaded. Also, when data is uploaded, it is conceivable that the uplink traffic accounts for most of the traffic while the downlink is required only for response signals. In such a case, if one channel assigned to each user is used to send each user's control command, the efficiency of data transmission becomes poor.

In recent years, the multi-carrier/DS-CDMA mobile communication system has been attracting attention as a mobile communication system that is capable of high-speed data transmission. This multi-carrier/DS-CDMA mobile communication system has a problem in that no scheme has yet been proposed about a channel structure that takes into account the above-described asymmetry in the amount of data transmission between the uplink and the downlink in high-speed data communications directed to multimedia or the like.

DISCLOSURE OF INVENTION

A general object of the present invention

is to provide an improved single carrier/DS-CDMA packet transmission method, an uplink packet transmission method in a multi-carrier/DS-CDMA mobile communication system, and a downlink channel
5 structure in a multi-carrier/DS-CDMA mobile communication system, which solve the problems of the conventional technology mentioned above.

The first object of the present invention relative to the single carrier/DS-CDMA packet
10 transmission method and transmission system is to provide multiplexing of a reservation demand packet and a data packet efficiently, to improve transmission efficiency, and further to realize a flexible bandwidth control of a channel wherein the
15 reservation demand packet and the data packet occupy according to changes in traffic amount.

In order to attain this object, the present invention is structured such that a predetermined time slot of part or all of spreading
20 codes is assigned to reservation demand packet transmission, and the reservation demand packet and data packet are time-multiplexed for transmission, in the single carrier/DS-CDMA packet transmission method which carries out bandwidth expansion of an
25 information symbol by a spreading code sequence, and carries out packet transmission using this spreading code.

Moreover, the single carrier/DS-CDMA packet transmission method which carries out the
30 bandwidth expansion of the information symbol by the spreading code sequence, and carries out the packet transmission using this spreading code is configured such that k pieces of spreading codes, where $0 < k < N$

and N represents the number of all spreading codes, are assigned to the reservation demand packet transmission, and the reservation demand packet and the data packet are code-multiplexed and transmitted,

5 the reservation demand packet transmission admission probability determined in advance is lowered when a channel occupancy rate of the data packet exceeds a predetermined value,

 the number of the spreading codes assigned
10 to the reservation demand packet transmission is decreased and the number of the spreading codes assigned to the data-packet transmission is increased when the channel occupancy rate of the data packet exceeds a predetermined value,

15 when the channel occupancy rate of the data packet exceeds a predetermined value, the reservation demand packet transmission admission probability determined in advance is first lowered, and if the channel occupancy rate of the data packet
20 still exceeds the predetermined value, even after lowering the reservation demand packet transmission admission probability, then subsequently, the number of the spreading codes assigned to the reservation demand packet transmission is decreased and the
25 number of the spreading codes assigned to the data-packet transmission is increased,

 when the channel occupancy rate exceeds the predetermined value, first the number of the spreading codes assigned to the reservation demand
30 packet transmission is decreased, and if the channel occupancy rate still exceeds the predetermined value, even after decreasing the number of the spreading codes assigned to the reservation demand packet

transmission, then subsequently, the reservation demand packet transmission admission probability determined in advance is lowered,

the channel occupancy rate of the data
5 packet is measured, and the number of spreading codes available for the reservation demand packet and the reservation demand packet transmission admission probability are determined,

the number of spreading codes available
10 for the reservation demand packet and the transmission admission probability above-mentioned are inserted into an information channel by time-multiplexing,

a short repetition period spreading code
15 (Short code) is used as a code to expand the bandwidth of the reservation demand packet and the data packet, and

as the code to expand the bandwidth of the reservation demand packet, the short repetition
20 period spreading code (Short code) is used, and a long repetition period spreading code (Long code) is used as the code to expand the bandwidth of the data packet.

The second object of the present invention
25 is to provide an uplink packet transmission method for a new multi-carrier/DS-CDMA mobile communication system, which can realize a packet transmission with a variable transmission speed.

In order to attain this object, the
30 present invention relative to an uplink packet transmission method in a multi-carrier/DS-CDMA mobile communication system that has n subcarriers (n being a natural number two or larger) is

structured such that frames that are segments for every fixed time are provided to each communication channel of the above-mentioned subcarriers, the frame is divided into time slots with F pieces (F
5 being a natural number, two or larger), and a mobile station transmits a packet to be transmitted to a base station by spreading by a spreading code in synchronous with the timing of the above-mentioned time slot.

10 Further, the uplink packet transmission method for the multi-carrier/DS-CDMA mobile communication system which has n subcarriers is structured such that:

the above-mentioned mobile station requires an
15 assignment of a time slot and a spreading code by transmitting a reservation demand packet to the above-mentioned base station which assigns a time slot and a spreading code to the demanding mobile station, and the above-mentioned mobile station
20 spreads a packet by spreading the packet by the spreading code and transmits in the time slot assigned by the above-mentioned base station,

the above-mentioned mobile station carries
out the packet transmission through a random access
25 to a time slot of one the above-mentioned communication channels without requesting the above-mentioned base station for an assignment of a time slot,

transmission speed of the above-mentioned
30 mobile station is changed according to a transmission volume of the packet which the above-mentioned mobile station transmits,

the above-mentioned base station assigns

k1 pieces (k1 being a natural number, and $k1 \leq F_{xn}$)
of the time slot for the above-mentioned reservation
demand packet transmission, and further assigns m1
pieces (m1 being a natural number, and $m1 \leq$ total
5 number of available spreading codes) of the
spreading codes, and the above-mentioned mobile
station transmits the reservation demand packet
spread by one of the assigned spreading codes in the
assigned time slot,

10 the above-mentioned base station changes
the number of the time slots k1 for the reservation
demand packet transmission according to the number
of the reservation demand packets during a
predetermined period from the above-mentioned mobile
15 station,

the above-mentioned base station changes
the number of the spreading codes m1 for the above-
mentioned reservation demand packet transmission
according to the number of the reservation demand
20 packets during the predetermined period from the
above-mentioned mobile station,

the above-mentioned base station changes
the number of the time slots k1 for the above-
mentioned reservation demand packet transmission,
25 and the number of the spreading codes m1 for the
above-mentioned reservation demand packet
transmission according to the number of the
reservation demand packets during the predetermined
period from the above-mentioned mobile station,

30 the above-mentioned base station notifies
a transmission limit of a reservation demand packet
to the above-mentioned mobile station, when there
are numerous reservation demand packets during the

predetermined period from the above-mentioned mobile station, the above-mentioned mobile station transmits reservation demand packets, following the limit,

5 the above-mentioned base station assigns k_2 pieces (k_2 being a natural number and $k_2 \leq F_{xn}$) of the time slot in which packet transmission is possible and an m_2 pieces (m_2 being a natural number and $m_2 \leq \text{total number of available spreading codes}$)
10 of the spreading code is further assigned for spreading a random access packet, by the above-mentioned mobile station accessing randomly for the above-mentioned mobile station to spread and transmit the random accessing packet by one of the
15 assigned spreading codes in the assigned time slot,

 the above-mentioned base station changes the number of the time slots k_2 for the above-mentioned random access packet transmission according to the number of packets during the
20 predetermined period from the above-mentioned mobile station which carries out random access,

 the above-mentioned base station changes the number of the spreading codes m_2 for the above-mentioned random access packet transmission
25 according to the number of packets during the predetermined period from the above-mentioned mobile station which carries out random access,

 the above-mentioned base station changes the number of the time slots k_2 for the above-mentioned random access packet transmission, and the
30 number of the spreading codes m_2 for the above-mentioned random access packet transmission according to the number of packets during the

predetermined period from the above-mentioned mobile station which carries out random access,

the above-mentioned base station notifies a transmission limit of a random access packet to the above-mentioned mobile station, when there are numerous packets during the predetermined period from the above-mentioned mobile station which carries out random access, and the above-mentioned mobile station performs random access following the limit,

the above-mentioned base station assigns p (p being a natural number, and $p \leq$ the total number of available spreading codes) pieces of spreading codes to the mobile station according to the magnitude of the transmission volume of the above-mentioned mobile station,

the above-mentioned base station assigns a spreading code having a different spreading factor to the above-mentioned mobile station according to the magnitude of the transmission volume of the above-mentioned mobile station, and

the above-mentioned base station performs assignment by changing at least two of the number of spreading codes p (p being a natural number and $p \leq$ total number of available spreading codes), spreading codes having different spreading factors, the numbers of time slots q (q being a natural number, and $q \leq F \times n$) according to the magnitude of the transmission volume of the mobile station.

The third object of the present invention is to provide a downlink channel structure that is capable of efficiently transmitting control information to each user in a situation where

information transmission volumes are asymmetrical between an uplink and a downlink in a multi-carrier/DS-CDMA mobile communication system.

In order to attain this object, the present invention, relative to the structure of the downlink channel in the multi-carrier/DS-CDMA mobile communication system that transmits spreading codes obtained by expanding bandwidth of information symbols by a spreading code sequence using two or more subcarriers that have a predetermined frequency interval, is structured such that two or more communication channels assigned to each of two or more subcarriers are divided for every predetermined time frame, multiplexed and assigned to each subcarrier, the two or more communication channels being used by a common control channel for two or more users, and a communication channel peculiar to each user.

According to the downlink channel structure in the multi-carrier/DS-CDMA mobile communication system such as above, either or both of user-peculiar information and common information is/are included in the common-control channel of each of the above-mentioned subcarriers and transmitted, when the information is transmitted from a base station to each user (mobile station).

Moreover, from a viewpoint that information used by each user when transmitting information to the base station should be efficiently transmitted to each user, the downlink of the present invention can be structured such that information for controlling transmission of each user's uplink is included in the above-mentioned

common-control channel. The information for
controlling transmission of each user's uplink can
include a transmission power control command to
control the transmission power of each user (mobile
5 station), a control command used to control a call
origination, and a control command to control, for
example, to control frequency, code (including a
spreading factor), and time to be used by each user.

Moreover, from a viewpoint that a response
10 to information transmitted by each user should be
efficiently transmitted to each user, the structure
of each downlink channel of the present invention
can include information relative to a response to
transmission of each user's uplink in the above-
15 mentioned common-control channel. The information
relative to the response to transmission of each
user's uplink can include, for example, a reply
signal ACK (Acknowledgement) and NACK (Non-
acknowledgement) to an uplink communication.

Moreover, from a viewpoint that broadcast
20 information to be transmitted in common to each user
should be transmitted efficiently, the present
invention can include the common broadcast
information to each user in the above-mentioned
25 common-control channel in the structure of each
downlink channel mentioned above. The broadcast
information to each user mentioned above can include
time, cell (base station) information, traffic
information about the cell to which the mobile
30 station is connected, road traffic information, and
broadcast information such as about television and
the like.

Moreover, from a viewpoint that the

downlink signal should be reliably demodulated according to a condition of a radio-transmission path between the base station and the user, the present invention can include a pilot symbol used
5 for demodulating the received signal at each user in the above-mentioned common-control channel in the structure of each above-mentioned downlink channel.

Moreover, the present invention allows an assignment of a common-control channel to one or a
10 plurality of code channels of part or all of the plurality of subcarriers in the structure of each above-mentioned downlink channel.

Moreover, the present invention allows the common-control channel in each subcarrier in the
15 structure of each above-mentioned downlink channel to accommodate different kinds of information.

Moreover, the present invention allows information that is included in the common-control channel assigned to each subcarrier to be time-
20 multiplexed into part of each time frame in the structure of each above-mentioned downlink channel.

Moreover, when information included in each common-control channel needs to be time-
multiplexed into part of each time frame, time-
25 multiplexing may be carried out with respect to the same timing portion of each time frame of each subcarrier, or may be carried out with respect to different timing portions of each time frame of each subcarrier as claimed in claim 10.

THE BEST MODE OF THE INVENTION

30 In the following, embodiments of the present invention will be described with reference to the drawings.

 The first embodiment of the present

invention is an embodiment concerning a single carrier/DS-CDMA packet transmission method.

Fig. 1 is an example of a channel structure of the first embodiment. Here, the horizontal axis and the vertical axis of each channel show time and power, respectively. Information signal is bandwidth-spread by a high-speed spreading code sequence, and the information signal whose bandwidth is expanded is transmitted by spreading codes Code1 through CodeN and time slots TS1 through TSM. At this occasion, a certain specific time slot is assigned to the reservation demand packet transmission.

In Fig. 1, among the spreading codes Code1 through CodeN and the time slots TS1 through TSM, the time slot TS1 is assigned to the reservation demand packet transmission and the other time slots TS2 through TSM are assigned to data packets.

The assignment to the reservation demand packet may be performed to part or all of the spreading codes.

Fig. 2 is another example of the channel structure of the first embodiment.

Here, the horizontal axis and the vertical axis of each channel show time and power, respectively. Bandwidth expansion of the information symbol is carried out by the high-speed spreading code sequence, and the information signal of which bandwidth is expanded is transmitted by the spreading codes Code1 through CodeN and the time slots TS1 through TSM. Here, a certain specific spreading code is assigned to the reservation demand packet transmission.

In Fig. 2, among the spreading codes Code1 through CodeN and the time slots TS1 through TSM, the spreading codes Code1 through Codek are assigned to the reservation demand packet transmission, and
5 the other spreading codes Code (k+1) through CodeN are assigned to the data packets.

Fig. 3 is an example of transmission admission probability control for reservation demand packet.

10 Usually, as shown in Fig. 3 (A), when a terminal (mobile station) requests to make a call, a reservation demand packet is transmitted at a certain transmission admission probability p ($0 < p \leq 1$).

15 Here, when a channel occupancy rate of the data packets exceeds a predetermined value, the transmission admission probability is lowered to q ($0 < q < p$), in order to avoid a collision of reservation demand packets, as shown in Fig. 3 (B).

20 Thereby, the collision probability of the reservation demand packets can be reduced and transmission efficiency can be raised.

Fig. 4 is an example of assignment control of the number of spreading codes available to a
25 reservation demand packet.

Here, the horizontal axis and the vertical axis of each channel show time and power, respectively. Bandwidth expansion of the information symbol is carried out by the high-speed spreading
30 code sequence, and the spread code of which bandwidth is expanded is transmitted by the spreading codes Code1 through CodeN and the time slots TS1 through TSM. Here, a certain specific

spreading code is assigned to reservation demand packet transmission.

Usually, as shown in Fig. 4 (A), the spreading codes Code1 through Codek are assigned to the reservation demand packet transmission.

When the channel occupancy rate of the data packets exceeds a predetermined value at this time, as shown in Fig. 4 (B), transmission efficiency can be raised by decreasing the number of the spreading codes currently assigned to the reservation demand packet, and increasing the number of the spreading codes assigned to the data packets.

In Fig. 4 (B), m pieces of the spreading codes ($m < k$) are reassigned to the data-packet transmission from those assigned to the reservation demand packet transmission.

That is, transmission efficiency can be raised by using the spreading codes Code $(k-m+1)$ through Codek previously assigned to the reservation demand packet will now be used by the data packet.

Fig. 5 is an example of assignment control of the number of the spreading codes available to the reservation demand packet transmission and the transmission probability of the reservation demand packet.

Here, the horizontal axis and the vertical axis of each channel show time and power, respectively. Bandwidth expansion of the information symbol is carried out by the high-speed spreading code sequence, and the spread code of which bandwidth is expanded is transmitted by the spreading codes Code1 through CodeN and the time slots TS1 through TSM. Here, a certain specific

spreading code is assigned to reservation demand packet transmission.

Usually, as shown in Fig. 5 (A), the spreading codes Code1 through Codek are assigned to the reservation demand packet transmission. Moreover,
5 usually, when a terminal requests to make a call, a reservation demand packet is transmitted at a certain transmission admission probability p ($0 < p \leq 1$).

10 In order to avoid a collision of reservation demand packets, when a channel occupancy rate of a data packet exceeds a predetermined value at this time, the transmission admission probability q ($0 < q < p$) for the reservation demand packet is
15 lowered first as shown in Fig. 5 (B).

If the channel occupancy rate of the data packet still exceeds the predetermined value, the transmission efficiency is raised by decreasing the number of the spreading codes currently assigned to
20 the reservation demand packet, and increasing the number of the spreading codes assigned to a data packet, as shown in Fig. 5 (C).

In Fig. 5 (C), m pieces of the spreading codes ($m < k$) are reassigned to the data packet from
25 the reservation demand packet.

That is, transmission efficiency can be raised by the data packet using the spreading codes Code ($k-m+1$) through Codek currently assigned to the reservation demand packet.

30 Fig. 6 is an example of assignment control of the number of spreading codes available to the reservation demand packets and the reservation demand packet transmitting probability.

Here, the horizontal axis and the vertical axis of each channel show time and power, respectively. Bandwidth expansion of the information symbol is carried out by the high-speed spreading
5 code sequence, and the information signal of which bandwidth is expanded is transmitted by the spreading codes Code1 through CodeN and the time slots TS1 through TSM.

Here, a certain specific spreading code is
10 assigned to the reservation demand packet transmission.

Usually, the spreading codes Code1 through Codek are assigned to the reservation demand packet transmission beforehand as shown in Fig. 6 (A).
15 Moreover, usually, when a terminal requests to make a call, the terminal transmits the reservation demand packet at a certain transmission admission probability p ($0 < p \leq 1$).

As shown in Fig. 6 (B), when a channel
20 occupancy rate of a data packet exceeds a predetermined value at this time, the number of the spreading codes currently assigned to the reservation demand packet is decreased, and the number of the spreading codes assigned to the data
25 packet is increased. In Fig. 6 (B), m pieces of the spreading codes ($m < k$) are reassigned to the data packet from the reservation demand packet.

If the channel occupancy rate of the data packet still exceeds the predetermined value, in
30 order to avoid the collision of reservation demand packets, the transmission admission probability q ($0 < q < p$) for the reservation demand packet is lowered as shown in Fig. 6 (C).

In this manner, the collision probability of the reservation demand packets is reduced and transmission efficiency is raised.

Fig. 7 is the example of a structure of the downlink broadcast channel in the first embodiment.

Here, the horizontal axis of a channel expresses time. Information about the number of spreading codes available to the reservation demand packet and the transmission admission probability is inserted into the broadcast channel, as a reservation demand packet by time-sharing

The channel is specified by the spreading code and the time slot.

Fig. 8 shows an example of a period of the spreading code for the bandwidth expansion of the reservation demand packet and the data packet in the first embodiment.

Here, both the reservation demand packet and the data packet are bandwidth-spread by a short repetition period spreading code.

Fig. 9 is another example showing periods of the spreading code for the bandwidth expansion of the reservation demand packet and data packet in the first embodiment.

Here, the data packet is bandwidth-expanded by a long repetition period spreading code, and the reservation demand packet is bandwidth-expanded by the short repetition period spreading code.

The first implementation of multiplexing the reservation demand packet and data-packet in the single carrier/DS-CDMA uplink packet transmission by

the first embodiment is shown in Fig. 10.

Fig. 10 (A) shows a channel structure, Fig. 10 (B) shows a normal situation, and Fig. 10 (C) is a drawing that shows a control of the transmission admission probability for the reservation demand packet when a channel occupancy rate of a data packet exceeds a predetermined value.

Fig. 10 shows a control of the reservation demand packet transmission admission probability corresponding to Fig. 3, using the packet multiplexing method shown in Fig. 1 and the downlink broadcast channel structure shown in Fig. 7.

In the first implementation of the first embodiment, a certain specific time slot is assigned to the reservation demand packet transmission. In a situation where a terminal transmits at the reservation demand packet transmission admission probability p ($0 < p \leq 1$), a base station measures a channel occupancy rate of the data packets, and when the value exceeds a predetermined value, the base station transmits a command which performs a control to lower the reservation demand packet transmission admission probability to q ($0 < q < p$) by inserting the command into a downlink broadcast channel by the time-multiplexing.

The second implementation of multiplexing the reservation demand packet and the data-packet in the single carrier/DS-CDMA uplink packet transmission of the first embodiment is shown in Fig. 11.

Fig. 11 (A) shows a channel structure, Fig. 11 (B) shows a normal situation, and Fig. 11 (C) is a drawing showing a reservation demand packet

transmission admission probability control when the channel occupancy rate of the data packet exceeds a predetermined value.

Fig. 11 shows a control of the reservation demand packet transmission admission probability corresponding to Fig. 3, using the packet multiplexing method shown in Fig. 2 and the downlink broadcast channel structure shown in Fig. 7.

A certain specific spreading code is assigned to the reservation demand packet transmission in the second implementation of the first embodiment. In a situation where a terminal transmits at a reservation demand packet transmission admission probability p ($0 < p \leq 1$), a base station measures a channel occupancy rate of a data packet, and when the value exceeds a predetermined value with, the base station transmits a command which performs control to lower the reservation demand packet transmission admission probability to q ($0 < q < p$) by inserting the command into a downlink broadcast channel by the time-multiplexing.

Fig. 12 shows the third implementation of multiplexing a reservation demand packet and a data-packet of the first embodiment in the single carrier/DS-CDMA uplink packet transmission.

Fig. 12 (A) shows a channel structure, Fig. 12 (B) shows a normal situation, and Fig. 12 (C) is a drawing showing control of the number of assigning spreading codes for the reservation demand packet transmission when a channel occupancy rate of the data packet exceeds a predetermined value.

Fig. 12 shows assignment control of the

number of the spreading codes available to the reservation demand packet corresponding to Fig. 4, using the packet multiplexing method shown in Fig. 2 and the downlink broadcast channel structure in Fig. 5 7.

In the third implementation of the first embodiment, a certain specific spreading code to reservation demand packet transmission is assigned. In a situation where k pieces of spreading codes are assigned to the reservation demand packets, a base station measures the channel occupancy rate of the data packets, and when the value exceeds a predetermined value, the base station transmits a command which performs control to reduces the number of spreading codes assigned for reservation demand packet transmission to $k-m$ ($0 < m < k$) by inserting the command into the downlink broadcast channel by the time-multiplexing. 10 15

The fourth implementation of multiplexing the reservation demand packet and the data-packet in the single carrier/DS-CDMA uplink packet transmission by the first embodiment is shown in Fig. 13. 20

Fig. 13 (A) shows a channel structure, Fig. 13 (B) shows a normal situation, Fig. 13 (C) shows the reservation demand packet transmission admission probability control when a channel occupancy rate of a data packet exceeds a predetermined value, and Fig. 13 (D) shows assignment control of the number of spreading codes available to the reservation demand packet transmission when the channel occupancy rate of the data packet exceeds the predetermined value, even after the reservation demand packet 25 30

transmission admission probability control is carried out.

Fig. 13 shows control of the reservation demand packet transmission admission probability and the number of spreading codes assignable for the reservation demand packet transmission corresponding to Fig. 5, using the packet multiplexing method shown in Fig. 2, and the downlink broadcast channel structure Fig. 7.

In the fourth implementation of the first embodiment, a certain specific spreading code is assigned to the reservation demand packet transmission. Where a terminal is transmitting at the reservation demand packet transmission admission probability p ($0 < p \leq 1$) and the number of the spreading codes standing at k , a base station measures the channel occupancy rate of the data packet, and when the measured value exceeds a predetermined value, the base station transmits a command which performs control to lower the reservation demand packet transmission admission probability to q ($0 < q < p$) by inserting the command into the downlink broadcast channel by the time-multiplexing.

When the channel occupancy rate of the data packet still exceeds the predetermined value even after this operation is performed, the base station transmits a command that performs control to reduce the number of spreading codes assigned for the reservation demand packet transmission to $k-m$ ($0 < m < k$) by inserting the command into the downlink broadcast channel by the time-multiplexing.

The fifth implementation of multiplexing a

data-packet and a reservation demand packet in the single carrier/DS-CDMA uplink packet transmission of the first embodiment is shown in Fig. 14.

Fig. 14 (A) shows a channel structure, Fig. 14 (B) shows a normal situation, Fig. 14 (C) shows assignment control of the number of spreading codes for the reservation demand packet transmission when a channel occupancy rate of a data packet exceeds a predetermined value, and Fig. 14 (D) is a drawing showing the reservation demand packet transmission admission probability control when the channel occupancy rate of the data packet still exceeds the predetermined value even after the number of spreading code assignment control for reservation demand packet transmission has been carried out.

Fig. 14 shows the reservation demand packet transmission admission probability control corresponding to Fig. 6, and assignment control of the number of the spreading codes for the reservation demand packet transmission, using the packet multiplexing method shown in Fig. 2 and the downlink broadcast channel structure in Fig. 7

In the fifth implementation of the first embodiment, a certain specific spreading code is assigned to the reservation demand packet transmission. While a terminal is transmitting at the reservation demand packet transmission admission probability p ($0 < p \leq 1$) and the number of the spreading codes for the reservation demand packet transmission being k , a base station measures a channel occupancy rate of the data packet, and when the value exceeds a predetermined value, the base station transmits a command which performs

assignment control to reduce the number of spreading codes for the reservation demand packet transmission to $k-m$ ($0 < m < k$) by inserting the command into the downlink broadcast channel by the time-multiplexing.

5 If the channel occupancy rate of the data packet still exceeds the predetermined value after this operation is performed, the base station transmits a command that performs control to lower the reservation demand packet transmission admission
10 probability to q ($0 < q < p$) by inserting the command into the downlink broadcast channel by the time-multiplexing.

In addition, the first embodiment of the present invention is applicable to both an uplink
15 packet transmission and a downlink packet transmission.

Moreover, in the first embodiment, when a base station determines the number of spreading codes available for a reservation demand packet, the
20 base station notifies the information thereof to a mobile station, specifying the number of spreading codes, or a specific spreading code, as a reservation demand packet channel.

Next, the second embodiment of the present
25 invention will be described.

The second embodiment is an embodiment concerning an uplink in a multi-carrier/DS-CDMA mobile communication system.

Fig. 15 is a drawing showing an example of
30 a channel structure between a mobile station and a base station in the multi-carrier/DS-CDMA method.

A frequency bandwidth to be used is divided into n subcarriers f_1 - f_n (n being a natural

number of two or larger). Moreover, these subcarriers f_1 - f_n are used by time-sharing. Therefore, frames are set up to each subcarrier. (A frame is a segment for every fixed time, and a frame
5 length is set to T_F . The frames are common to all subcarriers.) Furthermore, the frames are divided into F pieces of time slots in time (F being a natural number of two or larger) TS_1 - TS_F (1 time-slot length $TS=T_F/F$).

10 Therefore, over all subcarriers, there are $F \times n$ pieces of the time slots in one frame.

A mobile station transmits a packet according to the timing of this time slot. Moreover, within the same time slot, a packet is multiplexed
15 by the principle of the code division (CDMA) by spreading with different spreading codes.

Therefore, by the channel structure of Fig. 15, simultaneous transmission of a plurality of packets, $F \times n \times$ (the number of multiplex spreading
20 codes) is attained.

In the example of Fig. 15, three packets are multiplexed by CDMA in the time slot TS_1 of the subcarrier f_1 .

Fig. 16 shows an example of an exchange of
25 control performed between a mobile station and a base station when packet transmission is carried out to the base station from the mobile station.

The mobile station first transmits a reservation demand packet to the base station, demanding an assignment of a time slot and a
30 spreading code for transmitting a packet (S101). To the assignment demand from the mobile station, the base station assigns a time slot on a communication

channel, and a spreading code (S102), and notifies the result to the mobile station (S103).

The mobile station spreads the packet with the assigned spreading code in the time slot
5 assigned from the base station, and transmits (S104).

Thereby, only the mobile station which was assigned the time slot and the spreading code can transmit by spreading the packet using the assigned spreading code in the assigned time slot.

10 If a large number of the time slots or a large number of the spreading codes are assigned, a large number of packets can be transmitted simultaneously, making a transmission capacity large.

Moreover, even when one time slot and one
15 spreading code are assigned, the mobile station uses the assigned spreading code and the time slot with priority, enabling a packet transmission in a large transmission volume as a result, if the transmission can be done periodically and reliably until
20 information which the mobile station is to transmit is finished.

Fig. 17 is a drawing showing an example of an exchange of control performed in a mobile station and a base station when packet transmission is
25 carried out to the base station from the mobile station. The mobile station carries out a random access to one of time slots of a communication channel, and transmits a packet (S111).

Here, if it succeeds in transmission of a
30 packet, the packet transmission will be ended (YES at S112). When it fails (NO at S112), the mobile station carries out a random access again to one of the time slots on the communication channel, and

transmits the packet (S111).

Thus, the method, wherein the packet transmission of the mobile station is carried out by randomly accessing one of the time slots of the communication channels, without requiring a time slot assignment of the above-mentioned base station, is suitable when carrying out a packet transmission in a small transmission volume from the mobile station to the base station.

Fig. 18 is a drawing showing an example of an exchange of control performed in the mobile station and the base station for changing a transmission speed according to a volume of packet transmissions that the mobile station is to transmit.

When the mobile station transmits a reservation demand packet to the base station and requires an assignment of a time slot and a spreading code first, the volume of the transmission is also communicated (S120).

Based on the information about the assignment demand and the transmission volume from the mobile station, the base station assigns a time slot and a spreading code on a communication channel according to the transmission volume of the mobile station, and notifies the result to the mobile station (S121).

The mobile station transmits packets based on the notified result (S122).

Thereby, if the transmission volume of the packets which the mobile station is to transmit is large, the base station will allocate a time slot that is capable of transmitting the big transmission volume (for example, two or more time slots) and a

spreading code (for example, two or more spreading codes, and a spreading code of a small spreading factor), and if the transmission volume which the mobile station needs is small, the base station will
5 allocate a time slot and a spreading code accordingly.

In this manner, the base station assigns a time slot and a spreading code adaptively according to the transmission volume of the mobile station.

10 As for the mobile station, a transmission speed according to the transmission volume is attained.

Next, a description will follow as to how the base station assigns a time slot and a spreading
15 code for the reservation demand packet transmission, when the mobile station transmits the reservation demand packet to the base station.

From the mobile station to the base station, a simultaneous transmission of a plurality
20 of packets of F_{xn} (the number of multiplexing of spreading codes) is attained as shown in Fig. 15.

In the present invention, some of these F_{xn} (the number of spreading multiplexing codes) are used for the reservation demand packet
25 transmission.

In Fig. 19, the base station assigns arbitrary k_1 pieces (k_1 being a natural number, and $k_1 \leq F_{xn}$) of time slots as the reservation demand packet transmission time slots out of the F_{xn} pieces
30 of time slots that are present in one frame. Then, the mobile station spreads the reservation demand packet by one of m_1 pieces (m_1 being a natural number, and $m_1 \leq$ total number of available spreading

codes) of spreading codes determined beforehand by the base station and transmits the reservation demand packet in the time slot.

In Fig. 19, a time slot TS1 of a subcarrier f1, a time slot TS1 of a subcarrier f2, and a time-slot TS2 of a subcarrier f3 and the like are assigned as the reservation demand packet transmission time slots.

In the case of Fig. 20, an example of the channel structure is shown wherein time slots TS1 generated for every frame in all subcarriers are set up as the reservation demand packet transmission time slots ($k1=n$).

Fig. 20 is the case where the time slots TS1 in all the subcarriers f1-fn are set up as the reservation demand packet transmission time slots.

In the case of Fig. 21, an example of the channel structure is shown, wherein part of the time slot TS1 is set up as the reservation demand packet transmission time slot ($k1<n$) in all subcarriers. Selection of the $k1$ pieces of the time slots may be dispersedly from any subcarriers, or may be continuously.

In Fig. 21, the time slot TS1 of the subcarrier f3 is not assigned as a reservation demand packet transmission time slot.

In the case of Fig. 22, an example of the channel structure is shown, wherein all the time slots of one subcarrier are set up as the reservation demand packet transmission time slots ($k1=F$). Here, the number of subcarriers that set up reservation demand packet transmission time slots may be two or larger.

In Fig. 22, all the time slots of the subcarrier f1 are assigned as the reservation demand packet transmission time slots.

5 In the case of Fig. 23, an example of the channel structure is shown, wherein some of the time slots of one subcarrier are set up as the reservation demand packet transmission time slots ($k_1 < F$). Selection of k_1 pieces of the time slots may be from dispersed time slots, or continuous time
10 slots.

In Fig. 23, TS1, TS2, TS4, and the like of the subcarrier f1 are assigned as the reservation demand packet transmission time slots.

When there are numerous reservation demand
15 packets during a predetermined period from a mobile station, a reservation demand may not be responded. Then, according to the number of the reservation demand packets the number of time slots, the number of spreading codes, and the like for the reservation
20 demand packet transmission are changed.

In the case of Fig. 24, it is a drawing showing an example of control performed in the base station when the base station is changing the number of reservation demand packet transmission time slots
25 k_1 (k_1 being a natural number, $k_1 \leq F \times n$) according to the number of the reservation demand packets during a predetermined period from the mobile station.

The base station measures the number of
30 the reservation demand packets transmitted from the mobile station during the predetermined period (S130).

If the measuring result indicates that the

number of the reservation demand packets is larger than a certain threshold (YES in S131), the number of the reservation demand packet transmission slots is increased, and the position of the time slot is notified to the mobile station (S133).

If the measuring result indicates that the number of the reservation demand packets is below the threshold (YES in S132), the number of the reservation demand packet transmission slots is decreased, and the position of the time slot is notified to the mobile station (S134).

If the number of the reservation demand packets is not larger than the threshold (NO in S131) and the number of the reservation demand packets is not below the threshold (NO in S132), the number of the reservation demand packet transmission slots is not changed.

The mobile station transmits a reservation demand packet according to the position of the reservation demand packet transmission time slot notified from the base station.

Fig. 25 is a drawing showing an example of control performed in the base station when the base station changes the number $m1$ ($m1$ being a natural number, and $m1 \leq$ total number of available spreading codes) of the spreading codes for the reservation demand packet transmission according to the number of the reservation demand packets from the mobile station during the predetermined period.

The base station measures the number of the reservation demand packets transmitted from the mobile station during the predetermined period (S140).

If the measuring result indicates that the number of the reservation demand packets is larger than a certain threshold (YES in S141), the spreading code m1 for spreading a reservation demand packet is increased, and its specification is notified to the mobile station (S143).

If the measuring result indicates that the number of the reservation demand packets is below the threshold (YES in S142), the number m1 of spreading codes for spreading the reservation demand packet is decreased, and its parameter is notified to the mobile station (S144).

When the number of the reservation demand packets is not larger than the threshold (NO in S141) and the number of the reservation demand packets is not below the threshold (NO in S142), the spreading code for spreading the reservation demand packet is not changed.

The mobile station chooses one from the spreading codes for the reservation demand packet transmission notified from the base station, and spreads and transmits the reservation demand packet.

Fig. 26 is a drawing showing an example of control performed in the base station when the base station changes the number of the above-mentioned reservation demand packet transmission time slots k1 (k1 being a natural number, and $k1 \leq F \times n$), and the number of the spreading codes for the reservation demand packet transmission m1 (m1 being a natural number, and $m1 \leq$ total number of available spreading codes) according to the number of the reservation demand packets from the mobile station during the predetermined period.

The base station measures the number of the reservation demand packets transmitted from the mobile station during the predetermined period (S150).

5 If the measuring result indicates that the number of the reservation demand packets is more than a certain threshold (YES in S151), "the number of spreading codes m1 for spreading a reservation demand packet is increased", "the number of
10 reservation demand packet transmission slots k1 is increased" or "both are increased", and the fact is notified to the mobile station (S153).

 If the measuring result indicates that the number of the reservation demand packets is below
15 the threshold (YES in S152), "the number of spreading codes m1 for spreading a reservation demand packet is decreased", "the number of reservation demand packet transmission slots k1 is decreased" or "both are decreased", and the fact is
20 notified to the mobile station (S154).

 When the number of the reservation demand packets is not larger than the threshold (NO in S151) and the number of the reservation demand packets is not below the threshold (NO in S152),
25 "the number of spreading codes for spreading a reservation demand packet" and "the number of reservation demand packet transmission slots" are not changed.

 The mobile station chooses one from the
30 positions of the reservation demand packet transmission time slots and spreading codes for the reservation demand packet transmission notified from the base station for spreading and transmitting a

reservation demand packet.

Fig. 27 is a drawing showing an example of control performed in the base station in the case of the base station limiting transmission of a reservation demand packet from the mobile station (for example, transmission of a reservation demand packet being restricted temporarily) since a possibility of inaccurate transmission of a reservation demand packet increases when the number of the reservation demand packets increases, and the mobile station transmitting a reservation demand packet according to the limit.

The base station measures the number of the reservation demand packets transmitted from the mobile station during a predetermined period (S160).

If the measuring result indicates that the number of the reservation demand packets is larger than a certain threshold with (YES in S161), a transmission limit for a reservation demand packet is made stricter than the current condition, and the fact is notified to the mobile station (S163).

If the measuring result indicates that the number of the reservation demand packets is below the threshold (YES in S162), the transmission limit of the reservation demand packet is made looser than the current condition, and the fact is notified to the mobile station (S164).

If the number of the reservation demand packets is not larger than the threshold (NO in S161) and the number of the reservation demand packets is not below the threshold, the transmission limit is not changed (NO in S162).

For a mobile station making a random

access, the base station assigns k_2 pieces (k_2 being a natural number, and $k_2 \leq F_{xn}$) of time slots for the packet transmission, and further assigns m_2 pieces (m_2 being a natural number, and $m_2 \leq$ total number of available spreading codes) of spreading codes for spreading a random access packet.

The mobile station spreads the random access packet by one of the assigned spreading codes and transmits in the assigned time slot.

10 As shown in Fig. 28, the base station assigns arbitrary k_2 pieces (k_2 being a natural number, and $k_2 \leq F_{xn}$) as random access packet transmission time slots out of the of the F_{xn} time slots that are present in one frame. And the mobile station spreads the random access packet by one of the m_2 pieces (m_2 being a natural number, and $m_2 \leq$ total number of available spreading codes) of spreading codes determined by the base station beforehand and transmits in the random access packet transmission time slots.

25 In Fig. 28, the time slot TS1 of the subcarrier f_1 , the time slot TS1 of the subcarrier f_2 , and the time-slot TS2 of the subcarrier f_3 and the like are assigned as the random access packet transmission time slots.

Fig. 29 shows an example of the channel structure wherein time slots of the time slot TS1 in all subcarriers generated for every frame are set up as the random access packet transmission time slots ($k_2=n$).

In Fig. 29, the time slots TS1 of all subcarriers are assigned as the random access packet transmission time slots.

Fig. 30 shows an example of the channel structure where the time slots of the time slot TS1 generated for every frame of some subcarriers are set up as the random access packet transmission time slots ($k_2 < n$). Selecting the k_2 pieces of the time slots may be from dispersed subcarriers, or from subcarriers adjacent each other.

In Fig. 30, the time slot TS1 of the subcarrier f3 is not assigned as a random access packet transmission time slot.

Fig. 31 shows an example of the channel structure where all the time slots of one subcarrier are set up as the random access packet transmission time slots ($k_2 = F$).

In Fig. 31, all the time slots of the subcarrier f1 are assigned as the random access packet transmission time slots.

Fig. 32 shows an example of the channel structure where part of time slots of one subcarrier are set up as the random access packet transmission time slots ($k_2 < F$).

In Fig. 32, the time slot TS1, the time slot TS2, and the time-slot TS4 and the like of the subcarrier f1 are assigned as the random access packet transmission time slots.

Selecting the k_2 pieces of time slots may be from dispersed time slots, or time slots adjacent each other.

If there are numerous random access packets during the predetermined period from mobile stations, a chance may arise that communication is not available. Then, according to the number of random access packets during the predetermined

period, the number of random access packet transmission time slots, a spreading code, and the like are changed.

In the case of Fig. 33, it is a drawing showing an example of control performed in the base station when the base station changes the number of random access packet transmission time slots k_2 (k_2 being a natural number, and $k_2 \leq F \times n$) according to the number of random access packets from the mobile stations during the predetermined period.

The base station measures the number of random access packets transmitted from the mobile stations during the predetermined period (S230).

If the measuring result indicates that the number of the random access packets is more than a certain threshold (YES in S231), the number of random access packet transmission slots is increased, and the position of the time slot is notified to the mobile stations (S233).

If the measuring result indicates that the number of random access packets is below the threshold (YES in S232), the number of the random access packet transmission slots is decreased, and the position of the time slot is notified to the mobile stations (S234).

If the number of the random access packets is not more than the threshold (NO in S231) and the number of the random access packets is not below the threshold (NO in S232), the number of the random access packet transmission slots is not changed.

The mobile station transmits a random access packet according to the position of the random access packet transmission time slot notified

from the base station.

Fig. 34 is a drawing showing an example of control performed in the base station when the base station changes the number of the spreading codes m_2 (5 m_2 being a natural number, and $m_2 \leq$ total number of available spreading codes) for the random access packet transmission according to the number of random access packets from the mobile station during the predetermined period.

10 The base station measures the number of the random access packets transmitted from the mobile stations during a predetermined period (S240).

 If the measuring result indicates that the number of random access packets is larger than a
15 certain threshold (YES in S241), the number of spreading codes m_2 for spreading a random access packet is increased, and its parameter is notified to the mobile station (S243).

 If the measuring result indicates that the
20 number of the random access packets is below the threshold (YES in S242), the number of the spreading codes m_2 for spreading the random access packet is decreased, and its specification is notified to the mobile station (S244).

25 When the number of random access packets is not more than the threshold (NO in S241) and the number of the random access packets is not below the threshold (NO in S242), the number of the spreading codes for spreading the random access packet is not
30 changed.

 The mobile station chooses one from the spreading codes notified from the base station for the random access packet transmission, and spreads

and transmits the random access packet.

Fig. 35 is a drawing showing an example of control performed in the base station when the base station changes the number of the above-mentioned random access packet transmission time slots k_2 (k_2 being a natural number, and $k_2 \leq F \times n$), and the number of the spreading codes for the random access packet transmission m_2 (m_2 being a natural number, and $m_2 \leq$ total number of available spreading codes) according to the number of the random access packets from the mobile station during the predetermined period.

The base station measures the number of the random access packets transmitted from the mobile stations during the predetermined period (S250).

If the measuring result indicates that the number of the random access packets is larger than the threshold (YES in S251), "the number of the spreading codes for spreading the random access packet m_2 is increased" or "the number of the random access packet transmission slots k_2 is increased" or "both are increased", and the fact thereof is notified to the mobile station (S253).

If the measuring result indicates that the number of the random access packets is below the threshold (YES in S252), "the number of the spreading codes for spreading the random access packet m_2 is decreased" or "the number of the random access packet transmission slots k_2 is decreased" or "both are decreased", and the fact thereof is notified to the mobile station (S254).

If the number of the random access packets

is not more than the threshold (NO in S251) and the number of the random access packets is not below the threshold (NO in S252), "the number of the spreading codes for spreading the random access packet" and
5 "the number of the random access packet transmission slots" are not changed.

The mobile station chooses one from the positions of the random access packet transmission time slots and the spreading codes for the random
10 access packet transmission, which are notified from the base station, and spreads and transmits the random access packet.

Fig. 36 shows an example of control performed in the base station when the base station
15 restricts transmission of a random access packet from a mobile station (for example, transmission is restricted temporarily) and the mobile station transmits the random access packet according to the limit, when the number of the random access packets
20 increases, since there is a possibility that transmission of the random access packets may not be performed accurately.

The base station measures the number of the random access packets transmitted from the
25 mobile station during the predetermined period (S260).

If the measuring result indicates that the number of the random access packets is larger than the threshold (YES in S261), a transmission limit of
30 the random access packet is made stricter than the current condition, and the fact thereof is notified to the mobile station (S263).

If the measuring result indicates that the

number of the random access packets below the threshold (YES in S262), the transmission limit of a random access packet is made looser than the current condition, and the fact thereof is notified to the
5 mobile station (S264).

The transmission limit is not changed, when the number of the random access packets is not larger than the threshold (NO in S261) and the number of the random access packets is not below the
10 threshold (NO in S262).

In the second embodiment of the present invention, a mobile station changes a transmission speed according to the magnitude of the transmission volume of packets that the mobile station is to
15 transmit. In the following, a mode of the change of the transmission speed according to the transmission volume is shown.

In Fig. 37, an example is shown wherein a mobile station 1 uses p pieces of spreading codes
20 for packet multiplexing and transmits the packets at a transmission speed p times as fast in comparison with a transmission speed of a mobile station 2.

Fig. 38 is a drawing showing an example which realizes a variable transmission speed by a
25 base station assigning a mobile station a spreading code, spreading factor of which is changed according to the transmission volume of the mobile station within one time slot TS of a communication channel.

Fig. 38 shows how the transmission speed
30 of the mobile station 1 is made SF times as fast as compared with the mobile station 2 (a chip rate being the same) by using a spreading code, spreading factor of which is $1/SF$ of the spreading code for

the mobile station 2, for spreading packets of the mobile station 1.

Fig. 39 is a drawing showing an example which realizes a variable transmission speed by the base station assigning arbitrary q pieces of time slots (q being a natural number, and $q \leq F \times n$) to a mobile station within one frame of a communication channel according to a transmission volume of the mobile station.

Fig. 40, Fig. 41, Fig. 42, and Fig. 43 describe an embodiment wherein how the base station performs an assignment by changing at least two of the number of spreading codes p , a spreading factor of the spreading code, the number of time slots q , according to the transmission volume of the mobile station.

In Fig. 40, the transmission speed of the mobile station 1 is set at $p \times SF$ times in comparison with the mobile station 2, by assigning the mobile station 1 p pieces of spreading codes that have a $1/SF$ spreading factor of the spreading factor of the spreading code of the mobile station 2, in addition to as described in Fig. 38

In Fig. 41, the transmission speed of the mobile station 1 is further set at $p \times q$ times of the mobile station 2 by assigning p spreading codes to each time slot of the mobile station 1, in addition to as described in Fig. 39.

Fig. 42 shows an example wherein the transmission speed of the mobile station 1 is set at $q \times SF$ times of the mobile station 2 by assigning the mobile station 1 spreading codes that have a $1/SF$ spreading factor of the spreading factor of the

spreading code of the mobile station 2, and further assigning q times as many time slots.

Fig. 43 shows an example wherein the transmission speed of the mobile station 1 is set at $p \times q \times SF$ times of the mobile station 2 by assigning q times as many time slot as the mobile station 2 to the mobile station 1, and further assigning p pieces of spreading codes that have a $1/SF$ spreading factor of the spreading factor of the spreading code of the mobile station 2 in each time slot of the mobile station 1.

Next, the third embodiment of the present invention will be described.

The third embodiment is an embodiment relative to downlinks in a multi-carrier/DS-CDMA mobile communication system.

A base station transmitting information to each user with a downlink channel structure of the third embodiment of the present invention is configured as shown in Fig. 44, for example. The multi-carrier/DS-CDMA method is used for this base station as an access method.

In Fig. 44, this base station includes a common-control channel generation unit 11, user channel generation units 12 (#1) through 12 (# m), a multiplexing unit 13, a multi-carrier modulation unit 14, and a transmitting unit 15. The common-control channel generation unit 11 carries out bandwidth expansion of a control information symbol of each user according to a specific spreading code sequence, and generates a spreading code corresponding to the control information symbol. Each of the user channel generation units 12 (#1)

through 12 (#m) carries out the bandwidth expansion of the information symbol which is to be transmitted to each user according to the spreading code sequence corresponding to each user, and generates
5 the spreading code corresponding to the information symbol.

The multiplexing unit 13 synthesizes the spread codes corresponding to the information symbol from each user channel generation units 12 (#1)-12
10 (#m), then the synthesized signal and the spread codes corresponding to the control information symbol from the above-mentioned common-control channel generation unit 11 are multiplexed according to a predetermined algorithm. The algorithm of this
15 multiplexing can be set up arbitrarily. For example, information can be multiplexed using time multiplexing wherein information is inserted periodically in every fixed period, frequency multiplexing wherein information is inserted into a
20 certain specific subcarrier, or code multiplexing wherein multiplexing is performed by a certain specific code, or any combination thereof.

The multi-carrier modulation unit 14 modulates so that the multiplexed signal from the
25 multiplexing unit 13 is distributed over a plurality (n pieces) of subcarrier (multi-carrier) components (the inverse discrete Fourier transform: IDFT). Then, the signal containing the two or more subcarrier components obtained in this multi-carrier modulation
30 unit 14 is transmitted to the transmitting unit 15 one by one, and the above-mentioned signal is transmitted from this transmitting unit 15 to each user (mobile station). A frequency interval of the

subcarriers used in the above-mentioned multi-carrier modulation unit 14 is set up at p times (p being a positive real number) of an updating frequency (chip rate) of each spreading code sequence used in the common-control channel generation unit 11 and each of the user channel generation units 12 (#1) through 12 (#m).

The above-mentioned common-control channel generation unit 11 is structured as shown in Fig. 45.

10 In Fig. 45, the common-control channel generation unit 11 includes an uplink transmission-control information generation unit 20 and a synthesizing unit 60. The uplink transmission-control information generation unit 20 generates
15 information for controlling a transmission from each user (mobile station), and includes a transmission power control information generation unit 21, a first transmission-control information generation unit 22, a second transmission-control information
20 generation unit 23, a channel allocation information generation unit 24, and a synthesizing unit 25.

The transmission power control information generation unit 21 generates a transmission power control command to perform the transmission power
25 control of an uplink of the user. The first transmission-control information generation unit 22 generates control information, such as frequency, the number of codes, a time slot, and transmitting permission probability of random access that are to
30 be assigned to a random access, based on traffic information and the like. The second transmission-control information generation unit 23 generates control information, such as frequency, the number

of codes, a time slot, and transmitting permission probability of random access that are to be assigned to a reservation demand packet, based on the traffic information and the like. The channel allocation
5 information generation unit 24 generates information, such as frequency, a code (a spreading factor is also included), and a time slot that are assigned to a user to whom a permission of transmission is to be issued in response to a reservation demand packet.

10 The transmission power control command from the above-mentioned transmission power control information generation unit 21 varies according to a state of a communication transmission channel between each user (mobile station), and serves as
15 control information peculiar to each user. On the other hand, each control information from the first transmission-control information generation unit 22 and the second transmission-control information generation unit 23 and information about the channel
20 allocation from the channel allocation information control unit 24 are pieces of information common to each user.

 The synthesizing unit 25 synthesizes each information bit from the transmission power control
25 information generation unit 21, the first transmission-control information generation unit 22, the second transmission-control information generation unit 23, and the channel allocation information generation unit 24 according to a
30 predetermined algorithm. The synthesized signal acquired in this synthesizing unit 25 is outputted from the uplink transmission-control information generation unit 20 as uplink transmission control

information. The control information from this
uplink transmission-control information generation
unit 20 and other common-control information are
synthesized in the synthesizing unit 60, and the
5 synthesized signal is outputted from the common-
control channel generation unit 11 as information
for controlling the transmission from each user.

Here, in the above, although a description
about a bandwidth expansion process by a spreading
10 code has been omitted, the bandwidth expansion
process-by the spreading code sequence of the above-
mentioned synthesized signal is performed in the
latter part of the above-mentioned synthesizing unit
60, and the above-mentioned control information is
15 outputted from the common-control channel generation
unit 30 concerned as a spreading code as mentioned
above.

Further, as shown in Fig. 46, the above-
mentioned common channel generation unit 11 can be
20 structured so that it includes a response
information generation unit 30.

In Fig. 46, the response information
generation unit 30 generates the response
information corresponding to uplink transmissions of
25 each user, and includes user response information
generation units 31 (1) through 31 (m) corresponding
to each user and a synthesizing unit 32. Each of the
user response information generation units 31 (1)
through 31 (m) generates response commands ACK and
30 NACK to the uplink packet from a corresponding user.
The synthesizing unit 32 synthesizes information
bits relative to the response commands from each of
the user response information generation units 31

(1) through 31 (m) according to a predetermined algorithm.

The synthesized signal from the synthesizing unit 32 is outputted from the response information generation unit 30 as response information for an uplink transmission. Here, the response information is synthesized with other common-control information (the control information from the uplink transmission-control information generation unit 20 shown in Fig. 45 may be included) in the synthesizing unit 60.

Further, as shown in Fig. 47, the common channel generation unit 11 can be structured such that a common broadcast information generation unit 40 is included.

In Fig. 47, the common broadcast information generation unit 40 includes a time information generation unit 41, a cell information generation unit 42, a traffic information generation unit 43, a road traffic information generation unit 44, a broadcasting information generation unit 45, and a synthesizing unit 46. The time information generation unit 41 generates the time information indicating the absolute time. The cell information generation unit 42 generates information such as ID information which specifies the cell (base station) concerned, information showing the position of the base station concerned, and information about base stations near the base station concerned.

The traffic information generation unit 43 generates traffic information based on uplink and downlink communication situations in the cell of the base station. The road traffic information

generation unit 44 generates information indicating road traffic situations of roads in the area of the cell (base station) concerned. The broadcasting information generation unit 45 generates other
5 information, such as television information and circumference information.

Each of the information generation units 41, 42, 43, 44, and 45 above-mentioned does not need to synchronize in generating the information. The
10 information may be generated with different periods according to the kind of the information.

Information bits generated at one or more of the information generation units 41, 42, 43, 44, and 45 mentioned above are synthesized by the
15 synthesizing unit 46 according to a predetermined algorithm. The synthesized signal from this synthesizing unit 46 is outputted from the common broadcast information generation unit 40 as common broadcast information. Further, the common broadcast
20 information is synthesized in the synthesizing unit 60 with other common-control information (which may include either or both of the response information from the response information generation unit 30 shown in Fig. 46 and the control information from
25 the uplink transmission-control information generation unit 20 as shown in Fig. 45).

Further, the common channel generation unit 11 can also be configured as shown in Fig. 48.

In Fig. 48, this common-control channel
30 generation unit 11 includes a pilot symbol generation unit 50 and a synthesizing unit 60. The pilot symbol generation unit 50 generates a pilot symbol known to all users in common for

synchronization, channel estimation, and the like. The pilot symbol from this pilot symbol generation unit 50 is synthesized by the synthesizing unit 60 with other common-control information (which may
5 include at least a kind of information of the control information from the uplink transmission-control information generation unit 20 shown in Fig. 45, the response information from the response information generation unit 30 shown in Fig. 46, and
10 the common broadcast information from the common broadcast information generation unit 40 shown in Fig. 47).

Structure of the downlink channel formed in the base station that is configured as mentioned
15 above, and employs the multi-carrier/DS-CDMA method is shown in Fig. 49.

In the example shown in Fig. 49, in each time frame at a predetermined time, while a common-control channel is assigned to one code channel in
20 each of n subcarriers 1 through n , communication channels are assigned to a plurality of code channels. Each channel (a common-control channel and communication channels) in each subcarrier is distinguished by the spreading code sequences (code)
25 used in the common-control channel generation unit 11 and the user channel generation units 12 (#1) through 12 (# m) mentioned above.

The common-control channel includes the information generated in the common-control channel
30 generation unit 11 that may include any one of or any combination of, for example, the pilot symbol (generated by the pilot symbol generation unit 50), the uplink transmission control information

(generated by the uplink transmission-control
information generation unit 20), the response
information to the uplink transmission (generated by
the response information generation unit 30), the
5 common broadcast information (the common broadcast
information generation unit 40).

Information (transmission data) which
should be transmitted to a user is assigned to each
communication channel such that the information
10 generated in each of the user channel generation
units 12 (#1)-12 (#m) is included in the
corresponding communication channel.

In addition, channels of one or a
plurality of the subcarriers can be assigned to each
15 user.

In the downlink channel structure
mentioned above, a common-control channel of each
subcarrier can be arbitrarily set up as to what
information is included, and as to whether
20 information is included in the common channel of all
the subcarriers.

In the following, another example of the
downlink channel structure that is similar to the
example shown in Fig. 49 is described, where a
25 common-control channel is assigned to one code
channel in each time frame in each of the n
subcarriers 1 through n, and communication channels
are assigned to a plurality of code channels.

In the example shown in Fig. 50,
30 information other than the pilot symbol (uplink-
control information, uplink response broadcast
information) is included in the common-control
channel of a specific subcarrier (for example, the

subcarrier 1). The pilot symbol may be included in the common-control channel of all the subcarriers, or in the common-control channel of discontinuous subcarriers.

5 In an example shown in Fig. 51, different subcarriers are assigned to common-control channels according to the kind of information to be included. For example, the uplink-control information is included in the common-control channel in the
10 subcarrier 1, the uplink response information is included in the common-control channel in the subcarrier 2, and the broadcast information is included in the common-control channel in the subcarrier n. Like the example shown in Fig. 50,
15 this example also allows the pilot symbol to be included in the common-control channel of all the subcarriers, or in the common-control channel of each discontinuous subcarrier.

 In an example shown in Fig. 52, any of or
20 any combination of the above-mentioned pilot symbol, the uplink-control information, the uplink response information and the broadcast information is included in the common-control channel of each subcarrier, not in each whole time frame but in a
25 predetermined time zone T. Consequently, the information included in the common-control channel in each subcarrier is transmitted for every predetermined period to the same timing.

 In the example shown in Fig. 53, above-
30 mentioned information is included in the common-control channel in each subcarrier, not in each whole time frame but in some time zones, like the example shown in Fig. 52. In this example, however,

the time zones T1, T2 through Tn differ for every subcarrier. Consequently, the information included in the common-control channel in each subcarrier is transmitted for every predetermined period at
5 different timings.

According to the downlink channel structure in the multi-carrier/DS-CDMA mobile communication system, as mentioned above, since various information can be transmitted to each user
10 by including the information in the common-control channel-that can be commonly used by all users, efficient transmission is attained compared with the case where the information is transmitted by an individual channel peculiar to a user.

15 If information (for example, the transmission power control information, the response information to each user, the channel allocation information, and the like) peculiar to each user is further included in the common-control channel, the
20 peculiar information to a plurality of users can be transmitted now by one common-control channel, and efficient information transmission will be attained.

In the third embodiment, in each example mentioned above, although the common-control channel
25 was assigned to one code channel of all subcarriers, the present invention is not limited to this. It is possible to assign a control channel to one, two or more code channels of two or more subcarriers, partly or wholly.

30 According to the first embodiment of the present invention, efficient multiplexing of a reservation demand packet and a data packet is realized by using a time slot and a spreading code

in a single carrier/DS-CDMA uplink packet transmission method. Further by the first embodiment, changes in traffic amount can be flexibly met also by controlling the number of the spreading codes
5 available to a reservation demand packet and the reservation demand packet transmission admission probability.

Moreover, the packet transmission method in the multi-carrier/DS-CDMA of the second
10 embodiment of the present invention realizes time-slot reservation type packet transmission, random access type packet transmission, and packet transmission of a variable transmission speed, enabling efficient transmission of signals of
15 various transmission volumes.

Further, according to the third embodiment of the present invention, any of information peculiar to each user and information common to all users can be included and transmitted by inserting
20 the information into the common-control channel in each above-mentioned subcarrier in a multi-carrier/DS-CDMA mobile communication system when information is transmitted from a base station to each user (mobile station). Therefore, efficient
25 transmission of control information to each user is now available even when there is an asymmetry in transmission information volumes between the uplink and the downlink in a multi-carrier/DS-CDMA mobile communication system.

WHAT IS CLAIMED IS

1. An uplink packet transmission method in a multi-carrier/DS-CDMA mobile communication system having n (n being a natural number equal to or more than two) subcarriers, comprising:

setting up frames that define constant intervals in each communication channel of the subcarriers, and further setting up time slots by temporally dividing each of the frames into F pieces (F being a natural number equal to or more than two), and

spreading, in a mobile station, a packet to be transmitted by spreading codes in synchronization with timing off the time slots, and transmitting the packet to the base station.

2. The uplink packet transmission method as claimed in claim 1,

said mobile station requiring said base station to assign time slots and spreading codes by transmitting a reservation demand packet as preparation for packet transmission,

said base station assigning time slots and spreading codes to the mobile station that demanded, and

said mobile station spreading the packet by the assigned spreading codes and transmitting the packet via the time slots assigned by said base station.

3. The uplink packet transmission method as claimed in claim 1, wherein said mobile station makes random access to one of time slots of the communication channels to transmit a packet, without requiring the base station to assign time slots.

4. The uplink packet transmission method as claimed in claim 1, wherein said mobile station changes transmission speed of the mobile station according to a transmission volume of a packet that the mobile station is to transmit.

5. The uplink packet transmission method as claimed in claim 2,

said base station assigning k_1 (k_1 being a natural number, and $k_1 \leq F_n$) time slots for the reservation demand packet transmission, and further assigning m_1 (m_1 being a natural number, $m_1 \leq$ a total number of available spreading codes) spreading codes for spreading the reservation demand packet, and

said mobile station spreading and transmitting the reservation demand packet by one of the assigned spreading codes in the assigned time slots.

6. The uplink packet transmission method as claimed in claim 5, wherein said base station changes, the number k_1 of the time slots for the reservation demand packet transmission according to the number of reservation demand packets sent from the mobile station during a predetermined period.

7. The uplink packet transmission method as claimed in claim 5, wherein said base station changes the number m_1 of the spreading codes for the reservation demand packet transmission according to the number of reservation demand packets sent from the mobile station during a predetermined period.

8. The uplink packet transmission method as claimed in claim 5, wherein said base station changes the number k_1 of the time slots for the reservation demand packet transmission and the number m_1 of the spreading codes for the reservation demand packet transmission according to the number of reservation demand packets sent from the mobile station during a predetermined period.

9. The uplink packet transmission method as claimed in claim 5, wherein the base station notifies the base station of a transmission limit of the reservation demand packet when numerous reservation demand packets are received from the mobile stations during a predetermined period, and the mobile station transmits the reservation demand packet according to the limit.

10. The uplink packet transmission method as claimed in claim 3, wherein said base station assigns k_2 (k_2 being a natural number, and $k_2 \leq F_n$) time slots as usable for packet transmission through random accessing by the mobile station, and further assigns m_2 (m_2 being a natural number, and $m_2 \leq$ a total number of available spreading codes) spreading codes for spreading a random access packet, and wherein the mobile station spreads a random access

packet by one of the assigned spreading codes and transmits the packet in the assigned time slots.

11. The uplink packet transmission method as claimed in claim 10, wherein the base station changes the number k_2 of the time slots for the random access packet transmission according to the number of random access packets sent from the mobile station during a predetermined period.

12. The uplink packet transmission method as claimed in claim 10, wherein the base station changes the number m_2 of the spreading codes for the random access packet transmission according to the number of random access packets sent from the mobile station during a predetermined period.

13. The uplink packet transmission method as claimed in claim 10, wherein the base station changes the number k_2 of the time slots for the random access packet transmission and the number m_2 of the spreading codes for the random access packet transmission according to the number of random access packets sent from the mobile station during a predetermined period.

14. The uplink packet transmission method as claimed in claim 10, wherein the base station notifies the base station of a transmission limit of random access packets when numerous random access packets are received from the mobile stations during a predetermined period, and the mobile station makes random accesses according to the limit.

15. The uplink packet transmission method as claimed in claim 4, wherein the base station assigns p spreading codes (p being a natural number, and p a total number of available spreading codes) to the mobile station according to a transmission volume of the mobile station.

16. The uplink packet transmission method as claimed in claim 4, wherein the base station assigns to the mobile station a spreading code having a spreading factor that varies according to a transmission volume of the mobile station.

17. The uplink packet transmission method as claimed in claim 4, wherein the base station assigns q time slots (q being a natural number, and $q \leq F_n$) to the mobile station according to a transmission volume of the mobile station.

18. The uplink packet transmission method as claimed in claim 4, wherein the base station performs assigning by changing at least two of a number p of spreading codes (p being a natural number, and $p \leq$ a total number of available spreading codes), spreading codes having different spreading factors, and a number q of time slots q (q being a natural number and $q \leq F_n$) according to a transmission volume of the mobile station.
