Use of hCG in controlled ovarian hyperstimulation

Field of Invention

The invention relates to the field of *in vivo* and *in vitro* assisted reproduction technologies (ART), specifically controlled ovarian hyperstimulation (COH) using gonadotropins.

Background of the Invention

Treatment of infertility by assisted reproduction technologies (ART) such as *in vitro* fertilisation (IVF) or IVF in conjunction with intracytoplasmic sperm injection (IVF/ICSI) and embryo transfer (ET) requires controlled ovarian hyperstimulation (COH) to increase the number of female gametes[1]. Standard regimens[2] for COH include a down-regulation phase in which endogenous luteinising hormone (LH) is suppressed by administration of a gonadotropin releasing hormone (GnRH) agonist followed by a stimulation phase in which follicular development (folliculogenesis) is induced by daily administration of follicle stimulating hormone (FSH), usually at about 150 IU/day. Other molecules having FSH activity may also be used. Alternatively stimulation is started after spontaneous or induced menstruation while preventing the occurrence of an LH surge by administration of a GnRH-antagonist, usually starting on about day 6 or 7 of FSH administration. In superovulation protocols for ART, multiple follicular development is the desired aim. When there are at least 3 follicles >16 mm (one of 18 mm), a single bolus of hCG (5-10,000 IU) is given to trigger ovulation. Oocyte recovery is timed for 36-38 hours after the hCG injection.

The rationale for the use of GnRH agonists and antagonists in this context is the prevention of an untimely LH surge that would cause premature ovulation and follicle luteinisation[3]. GnRH agonist regimens have become the accepted norm in the clinic. It has been found that long regimens (i.e., those started in the midluteal phase of the cycle preceding ovulation induction, or before) are associated with easier patient scheduling, greater follicle yield, and overall better clinical results.[4] The use of GnRH antagonists is relatively new to the clinic, but is expected to show similar

benefits, with the added advantage of a shorter treatment regimen.

The prolonged administration of GnRH agonists or the administration of GnRH antagonists results in profound suppression of endogenous LH. This situation, while not incompatible with follicle development, does not mimic the natural cycle. In the natural cycle, LH levels show a gradual increase several days before the peak at midcycle.

Several groups have explored the role of chorionic gonadotropin (CG) in ovulation induction and ART. As is well known and recognised in the art, techniques or methods of ovulation induction (OI) are distinct from methods of COH, although both may involve the administration of FSH.

Filicori *et al.* have investigated the role of low doses of hCG, as a surrogate for LH, in controlled ovarian hyperstimulation[5]. hCG administration (50 IU hCG/day) was started synchronously with FSH administration and was continued on a daily basis until ovulation was triggered with a bolus of hCG. The numbers of small (<10 mm), medium (10-14 mm) and large (>14 mm) follicles were comparable between a group receiving hCG and a control group receiving FSH alone, however, the cumulative dose of FSH and the duration of FSH stimulation were reduced in the hCG treated group.

Messinis *et al.* report ovulation induction in anovulatory women (WHO group I) using a regimen that uses daily doses of hMG (75 IU each of FSH and LH) during the stimulatory phase and single or multiple doses of hCG during the luteal phase. The pregnancy rate was found to be significantly increased in patients receiving multiple hCG doses during the luteal phase as compared to a control group that received only a single ovulation inducing/triggering dose of hCG[6].

Proper follicular development is of course essential for successful ART methods. However, there are some cases in which ovulation and fertilisation are achieved, and yet improper implantation of the embryo prevents pregnancy. In other cases, spontaneous abortion (miscarriage) occurs during the first trimester. Both these problems may be associated with conditions in the endometrium, which is quite sensitive to hormone levels.

Thus, it can be seen that even once follicular development, ovulation and fertilisation have occurred there is no guarantee of a successful pregnancy and problems with implantation and early miscarriage are often encountered.

In some patients, tendency to abort or failure to implant may eventually be overcome, but to do so requires repeated ART cycles, with consequent negative physiological and psychological effects on the patient. In other patients, these problems represent an essentially permanent stumbling block to pregnancy.

Methods for increasing implantation rates and decreasing early miscarriage rates, particularly in conjunction with COH, are thus highly desirable.

Summary of the invention

It is an object of the invention to provide an improved method of administration of gonadotropins for COH, leading to improved implantation rates and decreased miscarriage rates.

It is a further object of the invention to provide a method for increasing pregnancy rates, e.g. by improving implantation rates and/or decreasing miscarriage rates, in patients who are not undergoing COH, for example, in patients following a natural ovulatory cycle or in patients undergoing ovulation induction.

In a first aspect, the invention provides a use of human chorionic gonadotropin (hCG) or an analogue thereof, for the manufacture of a medicament for encouraging implantation and/or decreasing miscarriage rates of an embryo in a human patient, wherein said medicament is administered before ovulation or ovulation triggering.

In a second aspect, the invention provides a use of human chorionic gonadotropin (hCG) or an analogue thereof, for encouraging implantation and/or decreasing miscarriage rates of an embryo in a human patient, wherein said hCG or an analogue thereof is administered before ovulation or

ovulation triggering.

In a third aspect, the invention provides a use of human chorionic gonadotropin (hCG), or an analogue thereof, for the manufacture of a medicament for use in conjunction with controlled ovarian hyperstimulation (COH) in human patients using FSH, or an analogue thereof, for aiding implantation and/or decreasing miscarriage rates, wherein the medicament is to be administered starting before the 10th day after commencing FSH treatment.

In a fourth aspect, the invention provides a use of human chorionic gonadotropin (hCG), or an analogue thereof, in conjunction with controlled ovarian hyperstimulation (COH) in human patients using FSH, or an analogue thereof, for aiding implantation and/or decreasing miscarriage rates, wherein the hCG or an analogue thereof is to be administered starting before the 10th day after commencing FSH treatment.

In a fifth aspect, the invention provides a pharmaceutical composition for use in aiding implantation of an embryo and/or decreasing miscarriage rates, optionally and preferably in conjunction with COH, comprising 25-1000 IU hCG, or an analogue thereof, per dosage.

A further aspect of the invention provides hCG or an analogue thereof for use in conjunction with controlled ovarian hyperstimulation (COH) in human patients using FSH, or an analogue thereof, for aiding implantation and/or decreasing miscarriage rates, wherein the hCG or an analogue thereof, is to be administered starting before the 10th day after commencing FSH treatment.

In an alternative embodiment, the invention provides hCG or an analogue thereof for encouraging implantation and/or decreasing miscarriage rates of an embryo in a human patient, wherein said hCG or an analogue thereof is administered before ovulation or ovulation triggering.

In a yet further aspect, the present invention provides a method of

encouraging implantation and/or decreasing miscarriage rates in a patient, which method is used in conjunction with controlled ovarian hyperstimulation using FSH, or an analogue thereof, which method comprises the administration to the patient of hCG or an analogue thereof, wherein said administration starts before the 10th day after commencing FSH treatment.

The present invention also provides a method of encouraging implantation and/or decreasing miscarriage rates in a patient, which method comprises administering to the patient hCG or an analogue thereof, wherein said hCG or an analogue thereof is administered before ovulation or ovulation triggering.

In a further aspect, the invention provides a kit for use in COH comprising 12 or more, preferably 14 or more daily doses of FSH, preferably about 75-200 IU FSH/day, more preferably about 150 IU FSH/day, and 4 to 8, 5 to 8 or 6 to 8 daily doses of hCG, for example 4, 5, 6, 7 or 8 daily doses of hCG, preferably about 25-1000 IU hCG/day, more preferably about 50-100 IU hCG/day.

In a further aspect, the invention provides a kit for aiding implantation of an embryo and/or decreasing miscarriage rates, the kit comprising 4 to 8, 5 to 8 or 6 to 8 daily doses of hCG, for example 4, 5, 6, 7 or 8 daily doses of hCG, at about 25-1000 IU hCG/day, preferably at about 50-100 IU hCG/day. Such kits may or may not be used in conjunction with COH.

Preferably the kits and pharmaceutical compositions of the invention are designed for use in the methods and uses of the invention.

Detailed description of the invention

Human chorionic gonadotropin (hCG) is a heterodimeric glycosylated peptide hormone which is produced by the placenta during pregnancy. It appears in serum shortly after fertilisation, and acts to maintain the corpus luteum after LH secretion decreases, supporting continued secretion of oestrogens and progesterone and preventing menstruation. Because it is only present at significant levels in the pregnant female, it is not thought to

play a significant role in the natural ovulatory cycle. It is known that receptors for hCG exist in the gonads, the uterus, fallopian tubes, placenta and in endometrial and myometrial cells[7]. hCG has the longest half life of the gonadotropins[8].

The inventors have unexpectedly discovered that administration of hCG or an analogue at low doses during the stimulatory phase of ART cycles has a beneficial effect on pregnancy rates, e.g. by aiding or increasing implantation and/or by decreasing miscarriage rates. The expression "low doses" encompasses doses less than the dose conventionally used in a particular patient to trigger follicle maturation, i.e. final follicular maturation, just prior to ovulation ("the follicle (or ovulation) triggering dose"). The follicle/ovulation triggering dose of hCG (usually in the range of 5,000-10,000 IU hCG, will vary on a patient-to-patient basis.

As can be seen from the discussion of standard COH regimens above, the administration of this "high dose" or ovulation triggering dose of hCG is often referred to in the art as the ovulation triggering step, oocyte maturation step or ovulation stimulation step. Such an ovulation stimulation or triggering step or oocyte maturation step involving the administration of a high dose of hCG is however only carried out once adequate follicular development has been achieved during the stimulatory phase of the COH regime, i.e. the phase involving the administration of FSH or an analogue thereof to induce folliculogenesis. A major difference between the methods and uses of the present invention and the prior art regimens is that hCG is administered during the stimulatory phase, i.e. before adequate follicular development has been achieved and before ovulation occurs or is triggered, and is administered at doses below that which induce oocyte maturation and ovulation stimulation, i.e. at doses below the ovulation triggering dose. Such regimens of the present invention give rise to surprising advantages in terms of implantation and miscarriage. Thus, in accordance with the present invention the low doses of hCG are administered in conjunction with COH regimes during the stimulatory phase before adequate follicular development has occurred and before the final high ovulation triggering hCG dose is administered to trigger oocyte maturation and ovulation.

In aspects of the invention where the patients are not undergoing COH low doses of hCG are also administered during the phase of folliculogenesis, and before adequate follicular development has been achieved. Again these doses of hCG are below the ovulation triggering dose. As indicated above, such patients may have a natural ovulatory cycle, in which case the eventual administration of an ovulation triggering dose of hCG will not be necessary. However, some of the patients not undergoing COH which can be treated by the administration of low doses of hCG in accordance with the methods of the invention may not have a natural ovulatory cycle (e.g. those undergoing OI), in which case the administration of an ovulation triggering dose of hCG can be carried out once adequate follicular development is judged to have been achieved.

When hCG is used in the aspects of the invention described herein, the dosage should be in the range of 25-4000 IU hCG/day, preferably 25-1000 IU hCG/day, more preferably 30-1000 or 30-500 IU hCG/day, and particularly preferably 50-100 IU or 75-125 IU hCG/day or 75-100 IU hCG/day or 75 or 100 to 500 or 75 or 100 to 1000 IU/day. Such doses are below the ovulation triggering dose and, as described above, are also referred to herein as "low doses" of hCG. If an hCG analogue is used, the equivalent to these hCG doses should be administered.

As indicated above pharmaceutical compositions or kits which may contain such doses of hCG for use in the methods and uses of the invention, are also provided.

In aspects of the invention where hCG (or an analogue thereof) is used in conjunction with COH using FSH, or an analogue thereof, administration of hCG (or analogue) should begin before the 10^{th} day after starting treatment with FSH, more preferably before the 9^{th} day after starting treatment with FSH. Administration of hCG should preferably not be started until at least 3 days after beginning FSH treatment, for example between the 3rd and 10th day after starting FSH treatment, more preferably not until at least 5 or 6 days after beginning FSH treatment. Particularly preferably, administration of hCG should be started on or about the 7^{th} or 8^{th} day after commencement of FSH treatment. Thus, hCG is administered during the follicular phase

and preferred timepoints for administration of hCG are at or about the mid-follicular stage of the cycle, i.e. at least 5, 6, 7 or 8 days after commencement of FSH treatment.

The administration of hCG in accordance with the present invention may be a single bolus, in which case it should preferably take place on or about the 7th or 8th day after FSH treatment is started, and the dosage should preferably comprise 100-1000 IU hCG, more preferably 100-500 IU hCG or 150-600 IU hCG, and particularly preferably about 250 IU hCG. Administration as a single bolus has the advantage of convenience for both the practitioner and the patient.

Alternatively, administration of hCG in accordance with the present invention may be carried out on a daily basis until follicle maturation is triggered or ovulation is induced/triggered with the conventional bolus of hCG. For daily administration, the dosage should be in the range of 25-4000 IU hCG/day, preferably 25-1000 IU hCG/day, more preferably 30-1000 or 30-500 IU hCG/day, most preferably 50-100 IU or 75-125 IU hCG/day or 75-100 or 75 or 100 to 500 or 75 or 100 to 1000 IU/day. A daily regimen that starts on the 7th day after commencing FSH treatment, and which uses 50-100 IU hCG/day has been found to be particularly effective. It is also possible to administer hCG on a less frequent basis, for example every two, three or four days, preferably every two days, until ovulation is triggered. In such regimen doses such as those outlined above may be used, although a dose of 50-200 IU hCG is preferred.

From the above discussion it will be apparent that the hCG used in accordance with the present invention is administered starting before ovulation occurs or before ovulation is triggered, e.g. by the ovulation triggering dose of hCG, and is continued until ovulation occurs or is triggered. In all the regimens of the invention, the administration of hCG may, if desired, be continued after ovulation if this is thought to be of benefit to the patient.

The timing at which ovulation may be triggered by administration of the "follicle/ovulation triggering dose" of hCG will be well known to a person

skilled in ART regimens and can be determined accordingly. In general ovulation is triggered when follicle development is considered adequate for the type of regimen being used. The level of follicle development is generally determined by measuring the size of the follicles (e.g. by ultrasound) and the serum oestradiol (E_2) level of the patient. If the regimen in question is COH then because the aim of these methods is multiple follicular development to produce an increased number of mature follicles/oocytes, which are generally fertilised *in vitro* and reintroduced to the patient, then the timing of the ovulation triggering is likely to be slightly different than if the regimen in question is ovulation induction in which the aim is to produce one, or at the most two, mature follicles which are ovulated and fertilised *in vivo*. For example in embodiments involving COH regimens ovulation may be triggered with 5 000 to 10000, e.g. 10 000 IU of hCG when at least two follicles of ≥ 18 mm in diameter are detected and a serum level of 300 pg/ml oestradiol is attained. Alternatively, in embodiments involving COH regimes, ovulation may be triggered when the largest follicle has reached a mean diameter of at least 18 mm, there are at least two other follicles with a mean diameter of ≥ 16 mm (i.e. there are at least 3 follicles ≥ 16 mm and one of these is ≥ 18 mm) and the oestradiol (E_2) level is within an acceptable range for the number of follicles present (approximately 150 pg/ml/mature follicle). For OI, the ovulation triggering dose of hCG may be given when there is at least one follicle ≥ 17mm (and it may be witheld if more than three follicles are ≥ 15mm).

hCG has a comparatively long half life in the body. For this reason, when multiple doses are used care must be taken that accumulation does not lead to undesirably high levels. It is preferred that serum levels of hCG not rise substantially above 50 IU/L, preferably not above 25 IU/L and most preferably not above about 10 IU/L prior to administration of the ovulation inducing bolus. If hCG levels rise substantially above this level, the result is likely premature luteinisation. The pharmacokinetics of bolus injections of hCG after intramuscular and subcutaneous injection have been reported by Mannaerts *et al.*[9]

In aspects of the invention where FSH (or an analogue) is used in conjunction with COH techniques or regimens, appropriate doses and administration regimes will be apparent to a person skilled in the art and any

appropriate dose and administration regime may be used. For example FSH may be administered daily at a dose of at or about 75 to 250 or 75 to 200 IU/day, preferably at or about 150 to 200 IU/day, most preferaby at or about 150 IU/day. In some patients showing a decreased response to FSH it may be desirable to use doses of up to 600 IU/day. A typical regimen is as follows: the patient is started on 150 IU FSH/day. After 3 or 4 days, an ultrasound is performed to evaluate developing follicles. If follicular development is adequate the dose of 150 IU FSH/day may be maintained. If follicular development is inadequate the dose may be increased to 225, 300, 375, 450, 525 or 600 IU FSH/day. Preferably FSH administration continues until the ovulation triggering dose of hCG is given. Ideally, the cumulative dose of FSH should not exceed 6000 IU/cycle.

The terms "improved rate", "encouraging", "aiding", "increased rates", etc., as used herein in connection with an effect on implantation or pregnancy include any measurable improvement or increase in frequency of occurrence of implantation or pregnancy in an individual patient or group of patients treated in accordance with the present invention, for example when compared with the level or frequency of occurrence of implantation or pregnancy in one or more non-treated patients or when compared to the level or frequency of occurrence of implantation or pregnancy in the same patient observed at an earlier time point (e.g. comparison with a "base line" level). For example, in embodiments where hCG is used in conjunction with COH, a relevant comparison is to compare patients treated in accordance with these embodiments to groups of patients having conventional COH or the same patient having conventional COH. Preferably the improvement or increase will be a statistically significant one, preferably with a probability value of <0.05. Methods of determining the statistical significance of results are well known and documented in the art and any appropriate method may be used.

The terms "decreased", "decreasing", "reduction", "reducing", etc. as used herein in connection with an effect on miscarriage, refer to any measurable decrease or reduction in the frequency of occurrence of miscarriage in an individual patient or group of patients treated in accordance with the present invention, for example when compared with the frequency of occurrence of miscarriage in one or more non-treated patients or when compared to the

level or frequency of occurrence of miscarriage in the same patient observed at an earlier time point (e.g. comparison with a "base line" level). For example, in embodiments where hCG is used in conjunction with COH, a relevant comparison is to compare patients treated in accordance with these embodiments to groups of patients having conventional COH or the same patient having conventional COH. Preferably the decrease will be a statistically significant one, more preferably with a probability value of <0.05. Most preferably the uses and methods as described herein in accordance with the present invention result in the prevention of miscarriages. Thus the prevention of miscarriages is also encompassed by these terms.

The use of hCG according to the invention may be useful for any patient in which it is believed that infertility may be attributed to early miscarriage or failure to implant, regardless of whether the patient is receiving other exogenous gonadotropins.

Miscarriage is defined as expulsion of the foetus before it is capable of independent survival. Early miscarriage refers to those miscarriages that occur in the first month of foetal development. The methods and uses of the present invention have particular utility in reducing the levels of early miscarriage.

The uses of hCG according to the invention in conjunction with COH are usually used in conjunction with *in vitro* fertilisation techniques. However, it is possible that the uses of hCG in conjunction with COH as described herein may also be used in conjunction with *in vivo* fertilisation.

In addition, the use of hCG according to the invention may also be in conjunction with *in vivo* fertilisation in patients who are not undergoing COH, for example regimens involving both natural ovulation and ovulation induction regimens, for example using anti-oestrogens or aromatase inhibitors (i.e. regimens not involving the administration of exogenous gonadotropins). When used in patients receiving no other exogenous gonadotropins, hCG should be administered starting before ovulation is expected to occur in any given cycle, preferably starting on or about the 6th, 7th or 8th day after menses. A single bolus may be given (for example at the

doses described above for single bolus administration and in particular 100-500 IU hCG), or it may be given on a daily basis (for example at the doses described above for daily administration and in particular at 50-100 IU hCG), or every second day (for example at the doses described above and in particular at 50-200 IU hCG), until ovulation takes place either naturally or, if required, by triggering with an ovulation triggering dose of hCG as described above.

In embodiments of the invention where hCG is used in patients not undergoing COH, such patients may alternatively be undergoing OI using exogenous gonadotropins (e.g. exogenous FSH). Appropriate dosages of hCG for this use are as described elsewhere herein. Ovulation is triggered at the appropriate time by a high dose of hCG as described above.

Thus, as indicated above, it will be appreciated that as well as the use of hCG in accordance with the present invention being advantageous in conjunction with COH regimes using FSH, hCG can also be used to improve implantation and/or decrease miscarriage rates of an embryo in a human patient not undergoing a COH regime, but trying to improve their chances of a successful pregnancy. Such patients (or their partners) will generally have experienced fertility problems of some kind, i.e. have some level of infertility or sub-fertility. Alternatively, or additionally, the patients may have no obvious fertility problems in terms of ovulation and fertilisation but may display infertility due to a tendency to early miscarriage and/or failure to implant. Older women e.g. women over 35, where problems with implantation and higher levels of miscarriage are acknowledged, are also good candidates for this treatment.

In such patients ovulation may either occur naturally or can be induced by an ovulation induction regime rather than a COH regime, e.g. OI regimes involving aromatase inhibitors, etc. (which stimulate endogenous FSH secretion), or exogenous FSH administration as discussed above. Such OI regimes are standard and well described in the art.

In such uses not involving COH regimes, the timing of administration of the hCG is generally calculated from the day of the commencement of menses,

although in OI regimes using FSH the timing of administration can be calculated from the day of commencing the FSH treatment. Appropriate timings after mensus or after commencing FSH treatment are as discussed above. As discussed above, the hCG is administered starting before ovulation (which may be either natural ovulation or triggered by ovulation triggering doses of hCG), during the follicular phase and preferably in the mid-follicular phase of the cycle, e.g. 5 to 8 days after menses, e.g. 6, 7 or 8 days after menses, or at least 5 or 6 days after beginning FSH treatment, e.g. 5, 6, 7 or 8 days after beginning FSH treatment. Thus, it can be seen that although the treatment regimens in such patients are different from those undergoing COH using FSH, the preferred timing of administration of the hCG is similar, i.e. at or around the mid-follicular phase of the cycle.

Administration of hCG according to the invention is useful in those patients being treated with GnRH agonists or antagonists. hCG administration according to the invention is particularly useful in conjunction with IVF or IVF/ICSI. The method results in increased rates of implantation and pregnancies lasting past the first trimester. The use of hCG can lead to implantation even in patients who have previously demonstrated failure in IVF regimens due to problems not associated with ovulation.

The use of hCG according to the invention can be particularly useful in treating patients with low endogenous LH levels, such as patients suffering from hypogonadotrophic hypogonadism.

The use of hCG according to the invention can also be used in patients which have previously exhibited failure to become or remain pregnant using FSH alone, e.g. in standard COH or OI regimens.

Examples of other suitable patient groups are those suffering from PCOD (polycystic ovarian disease), inadequate luteal phase and immunological factors and patients 35 years old and older ("older patients"). Preferably the patients are not older than 45 years, more preferably not older than 42 years.

The hCG that is used may be from any source, provided it is not

contaminated with any materials (particularly other gonadotropins) which will substantially affect its action. Urinary hCG may be used, although it is preferred to use recombinant hCG (rhCG), because of its high purity.

Analogues of hCG include all molecules which exert the same physiological, biochemical or biological effects as hCG, and/or bind to the same receptors as hCG. Luteinising hormone (LH) is known to share some physiological actions with hCG, but for the purposes of this description, LH is considered to be excluded from analogues of hCG.

Some analogues of hCG include single chain hCG, in which the C-terminus of the β-subunit is fused to the N-terminus of the α-subunit (Sugahara et al., PNAS, 92, 1995, 2041-2045). Other examples of analogues are as disclosed, for example in European patent no. EP 0 322 226 (Applied Research Systems) , WO 92/22568 (University of Medicine & Dentistry of New Jersey), WO 96/05224 (Washington University) , WO 90/09800 (Washington University) , WO 93/06844 (Washington University) , WO 98/43999 (Washington University) , WO 99/25849 (Washington University) .

hCG may be detected by any appropriate technique, for example using radioimmunoassay, as described by Vaitukaitis *et al.*[10], as well as ELISA assays.[11] The bioactivity of hCG can be measured by any appropriate technique, for example, by the mouse Leydig cell bioassay.[12]

In embodiments of the invention where FSH is used, it will be understood by one of skill in the art that FSH may be substituted by a biologically active analogue, or by a compound that stimulates endogenous FSH secretion. In this latter class are included aromatase inhibitors, and anti-oestrogens such as tamoxifen and clomiphene citrate (CC). These compounds stimulate endogenous FSH secretion by removing the negative feedback exerted by oestrogen on the hypothalamus (either by antagonising oestrogen receptors, as is the case with CC and tamoxifen, or by greatly decreasing oestrogen concentrations, as is the case with aromatase inhibitors).

A particularly preferred form of FSH for use in conjunction with the use of hCG according to the invention is known as FSH-CTP. This long-acting

human FSH is described in WO 93/06844, and has a wild type FSH α-subunit and a β-subunit that consists of the wild type FSH β-subunit fused at its carboxyl terminal to the carboxy terminal peptide (CTP) of the β-subunit of hCG (residues 112-118 to position 145 of the native hCGβ sequence). Other types of FSH analogues include, for example single chain FSH analogues in which the β-subunit is fused to the CTP of hCG, which in turn is fused to FSH α-subunit, as described in WO 96/05224 (single chain FSH-CTP).

As for hCG described above, the FSH used in the methods of the invention can be from any source. Such sources will be well known to a person skilled in the field of ovulation induction and of COH procedures. A urinary preparation of FSH may be used, e.g. hMG which contains FSH and LH activity at a 1:1 ratio. Preferably recombinant FSH will be used (rFSH) because of its high purity.

Human menopausal gonadotropin (hMG) has been used to replace FSH during the stimulatory phase in ovulation induction and COH for IVF. hMG is a relatively crude hormonal extract from the urine of postmenopausal women which contains both FSH and LH activity (ratio 1:1). Non-proprietary hMG may contain as little as 2% of the active hormones and consequently as much as 98% of the protein content may be urinary contaminants. When hMG is used instead of FSH in the methods of the invention, an hCG supplementation as described above, may also prove beneficial, for example for aiding implantation and/or preventing or decreasing miscarriages. hCG administration should be started before the 10th day after commencing hMG treatment, more preferably before the 9th day after commencing hMG treatment, particularly preferably on or about the 7th or 8th day after commencing hMG treatment. Administration of hCG should preferably start after the 3rd day after commencing hMG treatment. Dosages and dosing regimens are as given for use of hCG in conjunction with FSH. A preferred dose is 150 IU/day, more preferably 50 or 100 IU hCG/day.

The invention will now be described in more detail in the following non-limiting Examples.

Examples

Stimulation protocol

Control group 1: The first day of menses, the patients were submitted to de-sensitisation by daily injections of decapeptyl (0.1 mg). After 14 days, a sonographic examination was performed and in the absence of cysts, stimulation was started with rFSH (150 to 200 IU/day). After 7 days, follicular growth was checked by sonography and E_2 blood concentration was measured. The patients were examined on a daily basis and ovulation was triggered with 10,000 IU of hCG when at least two follicles $\geq$ 18 mm in diameter were detected and a serum level of 300 pg/mL of E_2 was attained.

Control group 2: At the time of day 7 in control group 1, control group 2 received hMG (150 IU/day) in addition to the rFSH.

Experimental group: At the time of day 7 in the control group, the experimental group received 50-100 IU of hCG on a daily basis in combination with the rFSH until ovulation was triggered as above.

The oocytes were fertilised *in vitro*. Four hours later, they were rinsed and put into culture medium (ISM1). After 20 hrs, fertilisation was checked and the embryos remained in the same medium until 48hrs. They were then transferred into a second culture medium (ISM2). The 2 best embryos were then transferred to patients and the remaining were cultured until blastocyst formation was reached (day 5-6).

Results

The results are summarised in Tables 1, 2 and 3. Tables 1 and 2 show results comparing control group 1 (rFSH alone) with the experimental group (rFSH + hCG). Table 3 shows results comparing control group 2 (rFSH + hMG) with the experimental group (rFSH + hCG).

There was no difference in the lengths of the stimulation periods. E_2 levels were increased in the group receiving hCG. The transfer rates were similar in both groups: 92% with hCG Vs 86% in the control group, (p=0.1). Blastocyst formation from the supernumerary embryos was not different between the 2 groups (185/411=45% with hCG Vs 292/627=46.5% control, p=0.622). Implantation rates (24.5% hCG Vs 14.6% control, p=0.0134) as

well as pregnancy rates per transfer (37.5% hCG Vs 23.6% control, p=0.0246) were increased in the hCG group, yielding a mean number of 1.9 embryo per transfer.

Table 1: hCG low dose in stimulation with rFSH

	+hCG	No hCG
No. of patients	96	127
Rank (age)	2.2 (32.8 ± 4.1)	1.5 (32.1 ± 4.5) (p=0.1068)
Transfers	89 (92%)	109 (86%)
Stimulation (days)	11.7	12.3
Oocytes recovered	10	9.7
Embryos (m)	6.2 (62%)	5.4 (56%)
Implantations	43/175 (24.5%)	30/206 (14.6%) (p=0.0134)
Embryo/transfer	1.97	1.89
Pregnancies	36/96 (37.5%)	30/127 (23.6%) (p=0.0246)
Blastocysts	185/411 (45%)	292/627 (46.5%) (p=0.6221)

Table 2: hCG low dose in stimulation with rFSH

	+hCG	No hCG	Total
Pregnancies	109	230	339
Ectopics	2	6	8 (2.4%) (p=0.95)
Miscarriages	8 (7.3%)	36 (15.6%)	44 (13%) (p=0.03)
Total miscarriages + ectopics	10 (9,17)	42 (18.3)	52 (15.7) (p=0.03)

Table 3: hCG low dose in stimulation with rFSH Vs hMG

	FSH +hCG	hMG
Pregnancies	109	76
Ectopics	2	2
Miscarriages	8	13 (p=0.049)
Total miscarriages + ectopics	10	15 (p=0.049)

Claims:

1. A use of human chorionic gonadotropin (hCG), or an analogue thereof, for the manufacture of a medicament for use in conjunction with controlled ovarian hyperstimulation (COH) in human patients using FSH, or an analogue thereof, for aiding implantation and/or decreasing miscarriage rates, wherein the medicament is to be administered starting before the 10th day after commencing FSH treatment.

2. The use according to claim 1, wherein the medicament is to be administered starting before the 9th day after commencing FSH treatment.

3. The use according to any one of claims 1 or 2, wherein the medicament is to be administered at least 3 days after commencing FSH treatment.

4. The use according to claim 1, 2 or 3, wherein the medicament is to be administered starting on or about the 7th or 8th day after commencing FSH treatment.

5. The use according to any one of claims 1 to 4, wherein the medicament is to be administered at a dosage of 25-1000 IU hCG/day.

6. The use according to any one of claims 1 to 5, wherein the medicament is to be administered at a dosage of 50-100 IU hCG/day.

7. The use according to any one of claims 1 to 6, wherein the medicament is to be administered as a single bolus.

8. The use according to claim 7, wherein the single bolus is administered on or about the 7th or 8th day after commencing FSH treatment, and the bolus comprises 100-500 IU hCG.

9. The use according to any one of claims 1 to 6, wherein the medicament is to be administered on a daily basis until ovulation is induced.

10. The use according to any one of claims 1 to 9, wherein the COH is

carried out in conjunction with *in vitro* fertilisation or *in vivo* fertilisation.

11. The use according to any one of claims 1 to 10, wherein the patients suffer from low endogenous LH levels.

12. The use according to any one of claims 1 to 11, wherein the patients have previously exhibited failure to become or remain pregnant using FSH alone.

13. The use according to any one of claims 1 to 12, wherein the hCG is recombinant hCG.

14. The use according to any one of claims 1 to 12, wherein the hCG is urinary hCG.

15. The use according to any one of claims 1 to 12, wherein an analogue of hCG is used and wherein said analogue is a single chain hCG.

16. A use of human chorionic gonadotropin (hCG) or an analogue thereof, for the manufacture of a medicament for encouraging implantation and/or decreasing miscarriage rates of an embryo in a human patient, wherein said medicament is administered before ovulation or ovulation triggering.

17. The use according to claim 16, wherein the medicament is to be administered as a single bolus on or about the 7^{th} or 8^{th} day after menses.

18. The use according to claim 16, wherein the medicament is to be administered on a daily basis, starting on or about the 7^{th} or 8^{th} day after menses and continuing until ovulation occurs.

19. The use according to any one of claims 16 to 18, wherein the hCG is as defined in any one of claims 13 to 15.

20. The use according to any one of claims 1 to 15, wherein an analogue of FSH is used and wherein said analogue is FSH-CTP, or wherein FSH is replaced with an aromatase inhibitor or clomiphene citrate.

21. A pharmaceutical composition for use in conjunction with COH, for aiding implantation and/or decreasing miscarriage rates, comprising 25-1000 IU hCG, or an analogue thereof, per dosage.

22. The pharmaceutical composition according to claim 21, comprising 75-125 IU hCG, or an analogue thereof, per dosage.

23. The pharmaceutical composition according to claim 21 or 22, wherein the hCG is as defined in any one of claims 13 to 15.

24. A kit for use in COH comprising 12 or more daily doses of FSH or an analogue thereof, and 4 to 8 daily doses of hCG or an analogue thereof.

25. A kit for aiding implantation of an embryo and/or decreasing miscarriage rates, comprising 4 to 8 daily doses of hCG at about 25-1000 IU hCG/day or an analogue thereof.
